CHAPTER 69

Pediatric Stroke and Intracerebral Hemorrhage

Catherine Amlie-Lefond, Jeffrey Ojemann

PEARLS

- Childhood stroke includes arterial ischemic stroke, cerebral sinus venous thrombosis, and intracranial hemorrhage.
- Diagnosis of acute stroke in childhood is often delayed due to failure to detect neurologic deficit in a child, low clinical suspicion of stroke, frequency of stroke mimics, and delays in diagnostic imaging.
- Compared with adults, the causes of pediatric stroke are much more heterogeneous, and often risk factors, rather than definitive causes, are identified.
- Supportive care in an intensive care unit, with careful attention to optimizing cerebral perfusion and oxygenation, decreasing metabolic demands on the brain, and preventing early stroke recurrence, is critical.

Significance

The incidence of childhood stroke ranges from 2.3 to 13 per 100,000 children.[1,2] Following an episode of stroke, 10% of children die, approximately 10% to 20% will have another stroke, and most survivors will have long-term neurologic or neuropsychologic deficits, including emerging deficits over time. Childhood stroke encompasses arterial ischemic stroke, hemorrhagic stroke, and cerebral sinus venous thrombosis. Approximately half of childhood strokes are ischemic and half are hemorrhagic. The diverse etiologies, risk factors, presentations, treatments, and potential complications of acute stroke in childhood must be considered to minimize morbidity and mortality in the intensive care setting.

Arterial Ischemic Stroke

Acute arterial ischemic stroke (AIS) is defined as the acute onset of a neurologic

deficit consistent with infarction in a vascular territory, with imaging or pathologic confirmation. Secondary hemorrhage due to tissue and vascular injury within the ischemic core can occur (*hemorrhagic conversion*), but unlike hemorrhagic stroke, the initial event is ischemic.

Etiologies and Risk Factors

Approximately half of all children presenting with initial AIS have an underlying condition that increases the risk of stroke (symptomatic stroke) and the other half have cryptogenic stroke. After extensive evaluation, most children will have at least one risk factor for stroke identified. It is likely that most instances of AIS in childhood are multifactorial.

Cerebral Arteriopathy

Cerebral arteriopathy is well associated with primary and recurrent stroke.[3,4] In the Vascular Effects of Infection in Pediatric Stroke (VIPS) study, definite or possible arteriopathy was present on vascular imaging in 46% of all patients and in 55% of the subset of patients who were previously healthy—that is, had no previously known risk factors for stroke.[5] In addition, cerebral arteriopathy has been found in children with acute AIS who have other stroke risk factors such as congenital heart disease.[6]

Focal cerebral arteriopathy (FCA) is a discrete intracranial arterial stenosis that accounts for approximately one-quarter of arteriopathies in childhood AIS.[7,8] FCA has been well associated with varicella zoster virus infection.[9] A subset of FCA is transient cerebral arteriopathy (TCA), which is defined as FCA that improves or shows no progression after 6 months.[8]

Moyamoya is a progressive steno-occlusive disease of the distal internal carotid arteries and proximal middle cerebral arteries, and not infrequently the anterior cerebral arteries, associated with collateral formation at the base of the brain, producing the *moyamoya* (Japanese for "puff of smoke") configuration seen on a catheter cerebral angiogram. Moyamoya usually presents with AIS in childhood, whereas adults frequently present with hemorrhagic stroke. Moyamoya may be idiopathic, termed *moyamoya disease*, or occur in association with predisposing syndromes, such as sickle cell disease, trisomy 21, or neurofibromatosis type 1, termed *moyamoya syndrome* (Fig. 69.1). Moyamoya disease is likely a genetic disease, most probably polygenic, based on the high prevalence of moyamoya in Asia, as well as familial aggregation in 5% to 10% of cases.[10,11] The only effective treatment for moyamoya is surgical revascularization to decrease the risk of further transient ischemic attacks (TIAs) and ischemic and hemorrhagic stroke.[12,13]

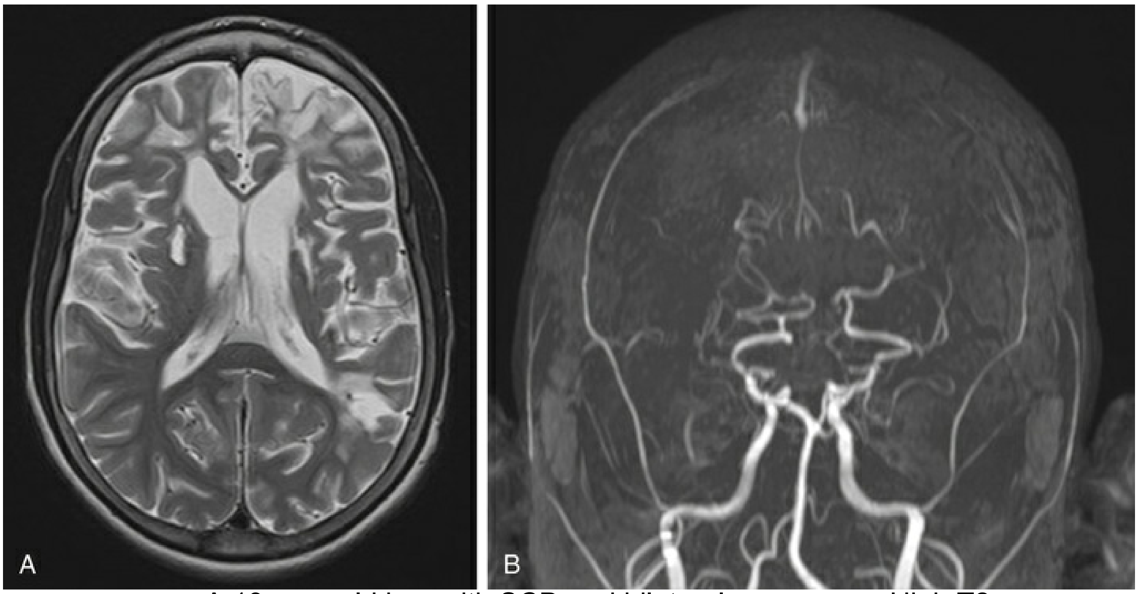

FIG. 69.1 A 13-year-old boy with SCD and bilateral moyamoya. High T2 signal and parenchymal volume loss represents sequelae of multiple infarcts seen in the bilateral anterior circulation (A). There is occlusion of the bilateral distal internal carotid arteries (B) and associated bilateral lenticulostriate and thalamoperforator collaterals consistent with moyamoya.

Cervicocephalic arterial dissection (CCAD) accounts for 7.5% to 20% of childhood AIS.[7,8,14] Because children with CCAD are at risk for recurrent stroke, anticoagulant therapy is recommended,[15] although antiplatelet therapy such as aspirin is also used, which is consistent with the recommendation of antiplatelet or anticoagulant treatment of CCAD in adults.[16] Often a history of trauma to the head or neck is obtained in children presenting with CCAD, such as can occur with sports injuries; however, CCAD can also present spontaneously. Dissection can also be complicated by subarachnoid hemorrhage due to aneurysmal dilation and recurrent dissection. Children with collagenopathies or elastinopathies such as Ehlers-Danlos syndrome, Marfan syndrome, Loeys-Dietz syndrome, and arterial tortuosity syndrome are at increased risk for initial and recurrent CCAD.[17]

Central nervous system (CNS) vasculitis is an inflammatory cerebral arteriopathy that can be primary, or idiopathic, or secondary to a systemic cause, most commonly systemic rheumatologic disease or infection. In childhood primary angiitis of the CNS (cPACNS), inflammation only involves the arteries of the CNS.[18] cPACNS can be divided into large-medium vessel disease, in which arteriopathy can be detected on cerebral catheter angiogram, and small vessel cPACNS, in which it is not visible on a catheter angiogram. Children with large-medium vessel cPACNS typically present with hemiparesis or aphasia, and stuttering onset of symptoms is common. Systemic inflammatory markers are often unremarkable in large-medium vessel cPACNS, and cerebrospinal fluid (CSF) pleocytosis or elevated protein is present in only one-third of children. Treatment of progressive large-medium vessel cPACNS requires immunosuppression. The use of anticoagulation or antiplatelet treatment may decrease the risk of stroke.[19]

In small vessel cPACNS, patients often present with diffuse neurologic deficits and headache. Brain magnetic resonance imaging (MRI) is usually abnormal, but

findings are nonspecific. Biomarkers including C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), leukocytosis, anemia, and thrombocytosis are frequently, but not consistently, abnormal. Brain biopsy is necessary to diagnose small vessel CNS vasculitis; however, this may yield a false-negative result in a significant number of patients.[19]

Secondary CNS vasculitis is a common manifestation of underlying systemic inflammatory diseases such as Takayasu arteritis, polyarteritis nodosa, and systemic lupus erythematosus. Arteritis is also commonly seen with acute bacterial meningitis, and heparin and aspirin have been used to prevent recurrent stroke in childhood bacterial meningitis.[20]

Varicella zoster virus (VZV) infection, both primary infection and reactivation, is associated with vasculopathy and stroke in children and adults.[9,21-23] VZV vasculopathy is diagnosed by the detection of VZV DNA or anti-VZV IgG antibody in CSF or both.[22] Treatment of VZV vasculopathy with both acyclovir and corticosteroids is recommended.[24]

Sickle Cell Disease

Stroke is a common complication of sickle cell disease (SCD), and without treatment, 11% of children will have a stroke by 20 years of age[25] (see also Chapter 90). The incidence of initial stroke is markedly decreased by regular red blood cell transfusions in children with elevated transcranial Doppler (TCD) velocity in the middle cerebral artery.[26,27] Following initial stroke, the risk of a recurrent stroke is approximately 20%, even with the use of chronic red blood cell transfusion. Many patients with SCD-associated stroke have an underlying cerebral arteriopathy, a risk factor for primary and recurrent stroke.[28-30] In addition, patients with SCD are at risk for aneurysmal hemorrhage.

The possibility of stroke needs to be considered in any child with SCD with transient or persistent focal weakness or deficit in addition to a history of new seizures or severe headache regardless of presence of pain. Blood should be sent for type and cross-match sickle negative, antigen selected, leuko-reduced (minor antigen-matched red blood cells if available) for exchange transfusion. Risk factors for stroke include increased blood pressure, lower hemoglobin concentrations, high leukocyte count, prior transient ischemic attacks, history of meningitis, presentation with seizure, surgery, priapism, acute anemia, recent acute chest syndrome and transfusion within the past 2 weeks, and a history of overt or silent stroke.[25,31,32]

An emergent head computerized tomography (CT) scan without contrast can be used to assess for possible hemorrhage or other intracranial process. Head MRI and magnetic resonance angiography (MRA) with diffusion-weighted imaging are the best ways to assess for possible acute stroke in a child with SCD and clinical presentation of possible stroke. Current guidelines recommend urgent erythrocyte transfusion in neuroimaging-confirmed stroke[33]; however, some recommend that transfusion not be delayed while awaiting confirmatory neuroimaging. There is a risk of ischemia due to increased viscosity if hemoglobin rises to >13 g/dL following transfusion.

Oxygen supplementation is used to maintain oxygen saturation greater than 93% through the completion of the transfusion and through the first night following to minimize nocturnal hypoxemia. Cooling blankets should be avoided in patients with

sickle cell disease. Cardiology consultation should be obtained prior to exchange transfusion if there is clinical suspicion of cardiac dysfunction, to assist with cardiac monitoring during exchange transfusion.

Although SCD is not an established contraindication to intravenous tissue plasminogen activator (tPA) in adults, there are no data with which to guide the use of tPA for stroke in children with SCD. As the pathophysiology of stroke in children with SCD may not be particularly responsive to thrombolysis, it is currently not recommended in this setting.

Congenital and Acquired Heart Disease

Cardioembolic stroke secondary to congenital and acquired cardiac disease accounts for almost one-third of AIS in children, with children with complex congenital heart disease (CHD) and right-to-left shunts at highest risk.[4] Among children with heart disease and stroke, one-quarter of strokes occurred in the setting of cardiac surgery or catheterization.[4] Not infrequently, the child with cardiac disease and stroke is acutely ill and sedated, and the stroke is not discovered until sedation or paralytics are weaned. Prothrombotic factors increase the risk of both initial[34] and recurrent stroke in the setting of CHD.[35] The risk of recurrent stroke in children with CHD is 27% at 10 years, with the highest risk immediately following the initial stroke.[35]

Hypercoagulable States

A prothrombotic state is identified in 13% of children with AIS,[4] and the risk of AIS increases when multiple thrombophilias are present or when combined with other risk factors such as CHD. Protein S deficiency, protein C deficiency, factor V Leiden mutation, antithrombin III deficiency, elevated lipoprotein (a), homocystinuria, and antiphospholipid antibodies have been associated with AIS in childhood[4,36] (Table 69.1).

TABLE 69.1

Risk Factors Reported in Acute Arterial Ischemic Stroke in Childhood

Cerebral Arteriopathy	Focal cerebral arteriopathy
	Moyamoya
	Cervicocephalic arterial dissection
	Primary CNS vasculitis
	Secondary vasculitis
	Varicella-associated vasculopathy
Hematologic Disorders	Sickle cell disease
	Iron deficiency anemia
	Thrombocytosis
	Leukemia
Heart Disease	Congenital heart disease
	Acquired heart disease
Hypercoagulable State	Protein C deficiency
	Protein S deficiency
	Factor V Leiden
	Homocystinemia
	Anticardiolipin antibodies
	Elevated lipoprotein (a)
Infection	Bacterial meningitis
	Varicella
	Mycotic meningitis
	Tuberculous meningitis

Drugs	Asparaginase
	Estrogen
	Illicit drugs (cocaine, methamphetamine)
Inflammatory/Autoimmune	Systemic lupus erythematosus
	Rheumatoid arthritis
	Vasculitis (as above)

Pathophysiology

Ischemic stroke occurs when blood supply to an area of the brain is not adequate for metabolic needs. This may occur due to occlusion of flow resulting from thrombus or embolus or due to critical stenosis. Decreased cerebral blood flow (CBF) below a critical threshold results in neuronal injury and potentially neuronal death. The central region with absence of CBF ("no flow") is the ischemic core, which will not survive. The surrounding area of ischemic penumbra is not irreversibly injured and potentially viable, but it will not survive without prompt restoration of blood flow (see also Chapter 68). The goal of reperfusion using intravenous tPA or acute endovascular intervention is to "rescue" the penumbra by restoring adequate perfusion to prevent cell death. The size of infarction is determined by the extent and duration of ischemia, cerebral perfusion pressure, and extent of collateral circulation. Fever may increase infarction size due to increased metabolic demands. Therefore strategies to minimize injury include ensuring adequate cerebral perfusion pressure and aggressively treating fever.

As energy failure at the cellular level results in neuronal hyperexcitability, seizures including status epilepticus can occur following acute stroke. Although prophylactic antiepileptic medication is not recommended, close monitoring for seizures, including the use of electroencephalography monitoring for subclinical seizures, is recommended. Seizures can be refractory in the immediate poststroke period.

Presentation

Recognition of stroke in childhood is challenging, as identifying neurologic deficits in children, particularly young children, is difficult and stroke is often not considered in the child presenting with acute neurologic deficit. In addition, mimics of childhood stroke are common, and the differential diagnosis is broad, including other diagnoses requiring urgent diagnosis and treatment such as brain tumors, hypertensive encephalopathy, demyelinating disorders, infection, postictal hemiparesis, and metabolic disorders.[37,38] Signs and symptoms of anterior circulation stroke in childhood include hemiparesis, hemisensory loss, aphasia, visual field cuts with gaze preference, and neglect. Posterior circulation strokes can present with ataxia, vomiting, vertigo, dysarthria, diplopia, and dysmetria. Diagnosis of cerebellar stroke is particularly challenging, as cerebellar stroke often presents with nonspecific symptoms such as headache and vomiting, or with ataxia, which mimics acute cerebellar ataxia. From 10% to 20% of childhood AIS cases are heralded by seizures. New neurologic deficit following a seizure in a child with acute stroke may be mistaken for postictal paresis.

Critical initial data to be collected in a child presenting with possible stroke include history of predisposing factors, time since the child was last seen well, recent trauma or infection, and medications. A baseline neurologic assessment such as the

pediatric version of the National Institutes of Health (NIH) Stroke Scale (PedNIHSS)[39] should be performed.

Neuroimaging

The potential for acute treatment and intervention will determine the urgency of neuroimaging studies. Head CT is usually the imaging modality used for a child presenting with acute neurologic symptoms or signs, due to speed and availability, and sensitivity for acute intracranial hemorrhage (ICH) and cerebral edema and impending herniation. Head CT is the first-line imaging study for the child with suspected ICH, trauma, or if MR is contraindicated; however, it is much less sensitive for early ischemic stroke than MRI using diffusion-weighted imaging (DWI).[40]

Although head CT and brain MRI will both evaluate for acute hemorrhage in children, the need to confirm AIS and rule out stroke mimics and the desire to limit radiation exposure results in MRI as the optimal first-line study in most cases. A rapid stroke MR protocol that can be done in 20 to 30 minutes may be used. Sequences should include DWI/apparent diffusion coefficient (ADC), which is sensitive for early ischemia, although not specific, and T1- and T2-weighted (or T2 fluid attenuation inverse recovery [FLAIR]) sequences and MRA of the head and neck (Fig. 69.2). FLAIR is less useful in children under 2 years of age due to immature cerebral myelination. Susceptibility weighted (SWI) or gradient echo (GE) will increase the sensitivity for detection of hemorrhage. Young children and those unable to cooperate will require sedation for acquired neuroimaging, which requires maintenance of blood pressure to optimize brain perfusion, particularly in the setting of flow-limiting arteriopathy.

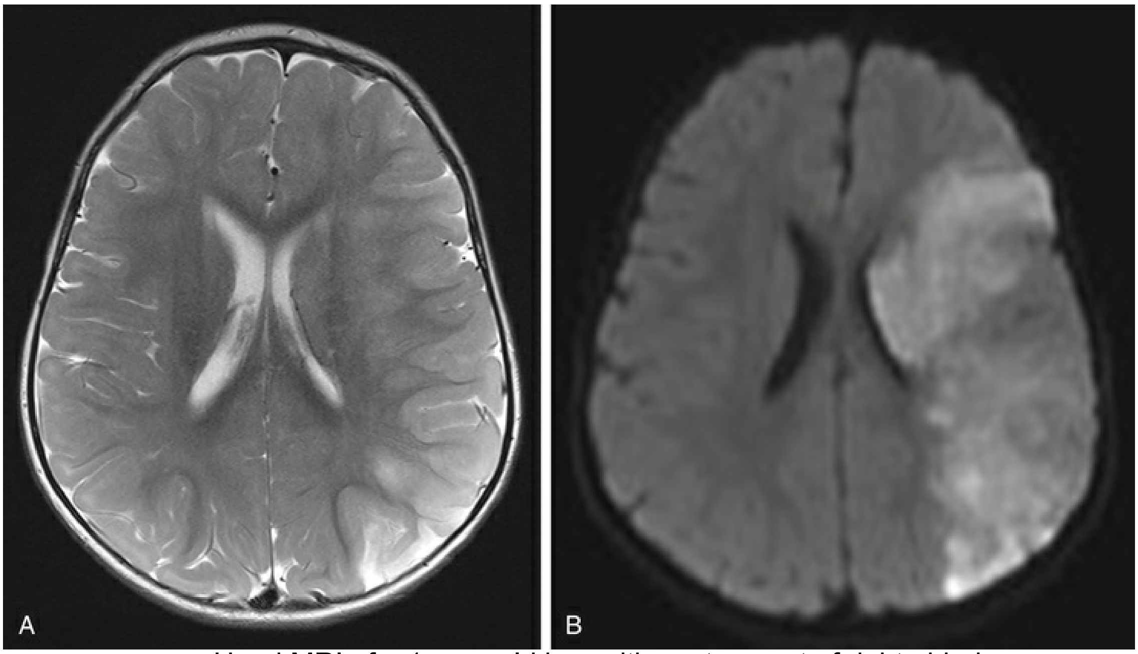

FIG. 69.2 Head MRI of a 1-year-old boy with acute onset of right-sided hemiplegia, with edema on T2 imaging (A) and restricted diffusion on DWI (B) in the left MCA territory.

MRA will reveal arteriopathy including stenosis and dissection in half to three-quarters of children with acute stroke,[3,7,41,42] but MRA cannot detect lesions in smaller arteries. Related imaging of the cerebral venous system is indicated if there are concerns about cerebral venous thrombosis. Vessel wall imaging is increasingly used in adults to evaluate the arterial wall itself, including for the presence of inflammation, rather than just the lumen as seen with MRA, CT angiography (CTA), and catheter angiograms, and is being used more often in children as well.

CTA of the head and neck can diagnose arteriopathy but requires sedation in the younger child and entails significant radiation exposure. For the latter reason, if a head MRA can be obtained, CTA may be avoided in some instances. If cerebral arteriopathy is strongly suspected despite a normal MRA, cerebral catheter angiography may be preferable to CTA due to greater sensitivity in diagnosing cerebral arteriopathy, particularly medium and small vessel arteriopathy.[43] It requires radiation and anesthesia; however, periprocedural complications are rare with experienced angiographers.[44] A cerebral catheter angiogram can be used for diagnosis of arteriopathy as well as for mechanical thrombectomy, treatment of aneurysm, and other neurointerventions.

Even when hyperacute treatment is not being considered, diagnosis of underlying etiologies such as CCAD, cardiac embolus, and cerebral sinus venous thrombosis (CSVT) will modify immediate treatment. Cerebral arteriopathy is an important predictor of primary and recurrent arterial ischemic stroke in childhood, and depending on etiology, treatment with antithrombotic medications, immunosuppressive agents, and antiviral medication may be indicated.

Laboratory Evaluation

Initial laboratory studies include complete blood count (CBC), electrolytes, blood urea nitrogen (BUN), creatinine, glucose, prothrombin time (PT), partial thromboplastin time (PTT), international normalized ratio (INR), ESR, blood gas and type, and screen or cross-match if intracranial hemorrhage is suspected, the child has SCD, or thrombolysis or thrombectomy is being considered (Table 69.2). Initial laboratory studies are initiated in a child with possible acute stroke. If the child is on anticoagulation, studies to assess therapeutic range include low-molecular-weight heparin (LMWH) activity and anti-Xa for LMWH, PTT for unfractionated heparin (UFH), and PT/INR for warfarin. Tests to rule out a hypercoagulable state should also be included (Table 69.3).

TABLE 69.2

Initial Laboratory Studies in Child With Possible Acute Stroke

Complete blood count
Coagulation studies: PT, PTT, INR
For child on anticoagulation:
— Low-molecula-weight heparin (LMWH) activity and anti-Xa for LMWH — PT/INR for warfarin
Electrolyte panel
Glucose
ESR
Renal and liver function studies
If clinically indicated:

— Pregnancy test — Urine or serum toxicology — Blood gas
Type and screen or cross if intracranial hemorrhage is suspected, the child has sickle cell disease, or thrombolysis or thrombectomy is being considered

TABLE 69.3

Laboratory Tests Considered in Childhood Arterial Ischemic Stroke

Laboratory Tests	Caveat
Hemoglobin S percentage	If child has known or suspected sickle cell disease
Iron and total iron-binding capacity	Severe iron deficiency anemia is a risk factor for stroke
Antinuclear antibodies (ANA)[a]	If clinical concern about underlying rheumatologic disease
Rheumatoid factor[a]	If clinical concern about underlying rheumatologic disease
Antiphospholipid antibody studies	Includes anticardiolipin antibody IgM, IgG, and IgA; anti–beta-2 glycoprotein IgM, IgG, IgA; and lupus anticoagulant
Factor V Leiden (FVL) mutation[a]	Most common cause of activated protein C (APC) resistance; 3%-8% of people with European ancestry carry one copy of the mutation
Prothrombin gene mutation (factor II/G20210A)[a]	More common in Caucasian population
Protein C activity and antigen	Can be lowered by warfarin, vitamin K deficiency, liver disease, disseminated intravascular coagulation (DIC)
Protein S activity and free antigen	Can be lowered by warfarin, vitamin K deficiency, liver disease, DIC, pregnancy; only the free protein S is functional as a c-factor for protein C
Activated protein C resistance (APCR)[a]	Rarely indicated as FVL accounts for most cases of APC resistance
5,10-Methylene tetrahydrofolate reductase (MTHFR)[a]	Only needs to be sent if homocysteine is elevated
Prothrombin time (PT), activated partial thromboplastin time (aPTT), andinternational normalized ratio (INR)	PT and INR measure extrinsic pathway of coagulation; PTT measures intrinsic pathway of coagulation
Antithrombin III (AT III) activity	Heparin and direct thrombin inhibitors can affect results; AT III should be checked if a patient is requiring higher heparin doses than expected, as anti-Xa activity is dependent on patient's AT III level
D-Dimer	May reflect clot burden
C-reactive protein (CRP)	Acute phase reactant to inflammation
Erythrocyte sedimentation rate (ESR)	Nonspecific measure of inflammation
Homocysteine[a]	Fasting sample preferred
β-HCG (pregnancy test)	Strongly consider in any female of childbearing age
Toxicology screen	Cocaine, methamphetamine, other vasoactive drugs, and cannabis associated with stroke
Lipoprotein (a)[a]	Does not need to be a fasting sample

[a]Rarely indicated in the acute period.

Laboratory tests considered in childhood AIS do not need to be sent urgently when maintaining an optimal hematocrit is critical, and not all patients require exhaustive testing. Urgent evaluations may include screening for systemic inflammatory disease (ESR, CRP, antinuclear antibodies), and a lupus inhibitor screen, antiphospholipid panel, and pregnancy test. Lumbar puncture may be indicated if there are concerns about infection; however, this may need to be delayed until the risk of intracranial hypertension has passed. If a cardioembolic etiology is suspected, urgent echocardiogram is indicated.

Treatment

Initial management includes optimizing cerebral perfusion and preventing hypoxemia, rescuing and minimizing expansion of the penumbra, and preventing complications. Children with acute stroke should be admitted to the pediatric intensive care unit (PICU) for a minimum of 48 hours for neurologic and medical monitoring and aggressive management of complications. Neurologic status should

be followed by the bedside nurse (hourly pediatric Glasgow Coma Scale and pupils until stable) as well as by medical staff. Ideally, the pediatric NIHSS[39] should be used to serially assess the patient. Urgent neuroimaging should be obtained for any neurologic deterioration.

Supportive Therapy

For the most part, therapy for childhood stroke is based on extrapolation from adult-based guidelines. Endotracheal intubation and mechanical ventilation are indicated for children with inadequate oxygenation or respiratory drive or an inability to protect their airway and may be needed to facilitate diagnostic or therapeutic procedures. Keeping the head of the bed flat may optimize cerebral perfusion. Blood pressure should be maintained with careful attention to adequate blood volume to avoid hypotension. Many children have transient hypertension following stroke, possibly representing a compensatory mechanism to maintain CBF, and permissive hypertension is usually recommended. If hypertension requires treatment, blood pressure should be lowered cautiously with close attention to worsening of neurologic status. Clinical and electrographic seizures should be treated, but there are no data to support seizure prophylaxis with antiepileptic medications. Fever should be treated aggressively to decrease metabolic demands on the brain. Cooling blankets should not be used in patients with sickle cell anemia.

Thrombolysis

There are minimal data on the use of tPA in acute childhood stroke, and currently the American Heart Association (AHA) recommends against the use of tPA in younger children outside of a clinical trial.[45] Due to the challenge of determining time of stroke onset and limitations of extrapolation from adult data to very young children, tPA for AIS should be used with great caution in children younger than 2 years of age and avoided in neonates. For older children and adolescents, data on safety and efficacy are limited, but tPA could be considered in selected patients. Published consensus-based guidelines and safety monitoring recommendations exist.[37]

Endovascular/Neurosurgical Treatment

If the patient was last seen at baseline within 6 hours and MRA or CTA shows occlusion in the internal carotid or M1 segment of the middle cerebral artery (MCA) or the vertebral and basilar artery, thrombectomy could be considered, particularly in an older adolescent. Although not approved by the Food and Drug Administration for use in children, studies of the safety and efficacy of mechanical thrombectomy in adults have been promising.[46-48] This procedure should be approached with caution, including full disclosure of the lack of data in children, and should only be performed by neurointerventionalists or interventional radiologists with pediatric experience. Urgent neurosurgical consultation for possible decompressive hemicraniectomy should be obtained promptly in children with malignant middle cerebral artery infarct (Fig. 69.3). Suboccipital craniectomy with dural expansion should be considered in patients with neurologic deterioration

due to edema from cerebellar infarction. In malignant infarction, monitoring of intracranial pressure (ICP) has not been shown to be helpful and may delay surgical treatment in these patients.

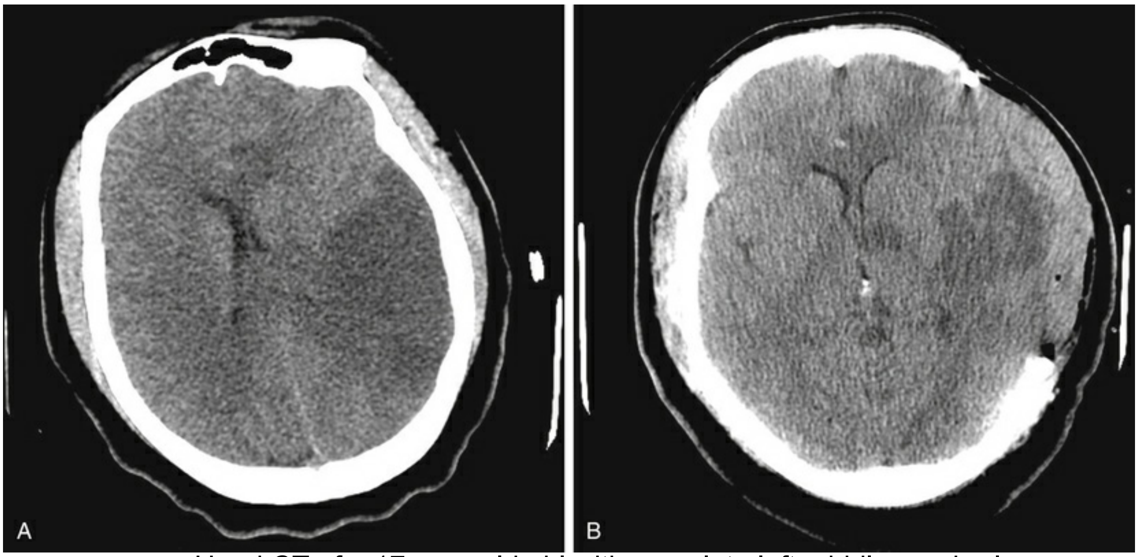

FIG. 69.3 Head CT of a 17-year-old girl with complete left middle cerebral infarct prior to (A) and following (B) decompressive hemicraniectomy.

Antithrombotic Therapy

A full review of the use of antithrombotic therapies in children is available in the *Chest* guidelines.[15] Anticoagulation is typically used in children with acute AIS without hemorrhage pending complete workup of potential etiologies to prevent recurrent stroke, which can occur early, particularly in the setting of dissection or cardioembolic stroke. Anticoagulation is usually initially achieved with continuous intravenous heparin, which can be reversed if necessary by protamine or fresh frozen plasma, with transition to LMWH when the child is stable. LMWH has more predictable pharmacokinetics and reduces the risk of heparin-induced thrombocytopenia, a serious antibody-mediated complication of heparin[49]; however, it cannot be reversed rapidly and has renal clearance, necessitating dosage adjustment in the setting of impaired renal function. For long-term anticoagulation, LMWH or warfarin is used. Warfarin has difficult-to-manage pharmacokinetics, and oftentimes LMWH is the anticoagulant of choice, despite the need for subcutaneous injection. Newer anticoagulants are currently being studied to treat adult stroke but have not been used widely in cases of pediatric stroke. Anticoagulation is usually continued in children with presumed cardioembolic stroke, significant thrombophilic states such as antiphospholipid syndrome, and cervical artery dissection.[15,45]

Aspirin inhibits platelet activity by irreversibly inhibiting cyclooxygenase-1 and is used based on consensus for stroke prevention in children not felt to require anticoagulation. A dose of 3 to 5 mg/kg/day is recommended acutely after contraindications such as ICH have been excluded.[45] Aspirin is often used for long-term stroke prophylaxis in children as well; however, optimal doses and duration

are unknown. The doses used for stroke prophylaxis are less than those associated with Reye syndrome[50] (Table 69.4).

TABLE 69.4

Published Guidelines for Antithrombotic Treatment of Childhood Acute Arterial Ischemic Stroke

Indication	American College of Chest Physicians (ACCP) guidelines, 2012[15]	American Heart Association Guidelines for Management of Stroke in Infants and Children, 2008[45]
Initial treatment	UFH or LMWH or aspirin 1–5 mg/day until cardiac etiology or arterial dissection ruled out	UFH or LMWH until etiology determined; aspirin 3–5 mg/kg/day for children without known risk of recurrent embolism or severe hypercoagulable disorder
Cardiac embolism with risk of recurrence (excluding native valve endocarditis)	LMWH	UFH or LMWH
Extracranial cervicocephalic arterial dissection	LMWH	UFH or LMWH
Sickle cell disease	Exchange transfusion with goal HbS <30%	Exchange transfusion and hydration
Intravenous tPA	Not recommended for children outside of research protocol	Generally not recommended outside of a clinical trial

Cerebral Sinus Venous Thrombosis

Cerebral sinus venous thrombosis (CSVT) occurs when thrombosis is present in the major venous sinuses draining the brain. Headache is the most common presenting symptom of CSVT. CSVT can result from multiple processes including venous stasis, hypercoagulable state, dehydration, and direct damage to the vessel wall in the venous system, which has slower blood flow. CSVT can involve the dural venous sinuses (superior sagittal, transverse, or sigmoid sinus), deep venous system (internal cerebral veins), or cortical dural veins. Multiple sinuses are involved in most children, with the transverse sinus most commonly affected followed by the sagittal sinus.[51] Potential complications due to CSVT include venous infarction, which occurs secondary to venous outflow obstruction, intracranial hypertension, cranial nerve palsies, and cerebral hemorrhage.

The incidence of CSVT in children age 1 month to 18 years is approximately 0.4/100,000/year,[52] although with advances in neuroimaging, this reported incidence may rise. Children with CSVT often present with nonspecific findings such as headache, seizures, increased ICP, and lethargy, although localizing signs such as cranial nerve palsies and hemiparesis may be present.

Etiologies and Risk Factors

Most children with CSVT have underlying risk factors identified, and multiple risk factors are often present.[51-57] Prothrombotic disorders are found in approximately half of children with CSVT.[52,53,57,58] The AHA guidelines note that children with CSVT may benefit from thrombophilia screening, which may impact care decisions (class IIb, level of evidence C).[45] Laboratory studies should be directed based on the medical history, and a family history of thrombophilia and thrombosis should be obtained. An abbreviated thrombophilia screen may be adequate in children with triggered CSVT, for example, following surgery involving the dural sinuses or

following head trauma (Table 69.5).

TABLE 69.5
Risk Factors Reported in Pediatric Cerebral Sinus Venous Thrombosis

Inherited Thrombophilias
G20210A mutation[54]
Factor V Leiden[54,66]
Protein C deficiency[54,66]

Neuroimaging

CSVT can be seen in some cases on CT scan and in particular contrast-enhanced CT scan; however, the sensitivity is poor. A clot may be visible on a nonenhanced CT scan as a dense clot sign. The delta sign, a triangular area of high contrast enhancement with a low attenuating center, may be present on enhanced CT scan.

This is best seen with sagittal sinus thrombosis. CT venography is sensitive for CSV\T but requires radiation and does not assess parenchyma well for venous congestion or infarct.

Head MRI and magnetic resonance venography (MRV) are the preferred diagnostic modalities. MRI is the best modality to detect associated parenchymal abnormalities. The head MRI and MRV should be ordered with and without contrast, with the caveat that contrast is not needed if the radiologist is satisfied with the noncontrast images. Contrast may be particularly helpful in borderline or unusual cases or with suspected infection as the etiology. Rarely, a high-resolution CT venography or catheter angiogram will be indicated.

Laboratory Evaluation

Initial laboratory studies include CBC, electrolytes, BUN, creatinine, glucose, PT/PTT, ESR, and antithrombin III activity in preparation for possible heparin administration, as well as a pregnancy test in females of childbearing age. Urgency of evaluation for risk factors for CSVT will be determined by history and presentation.

Treatment

Supportive measures include adequate ventilation, hydration, treatment of infection if indicated, and control of seizures. Children with CSVT may rapidly progress to obtundation, particularly when the deep venous system is involved (Fig. 69.4), and even death. Signs and symptoms of infection of the head and neck should be sought and broad-spectrum antibiotics started when appropriate. Seizures have been reported in over half of children with CSVT.[52] Children with acute symptomatic CSVT should be cared for in the PICU, particularly while anticoagulation is being initiated.

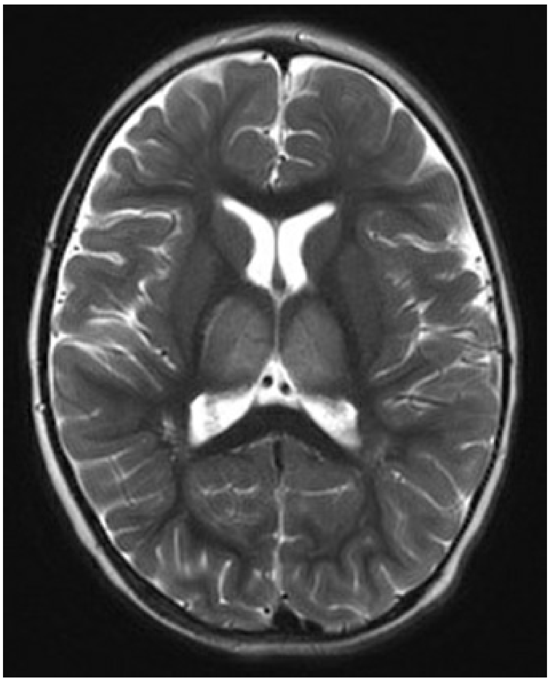

FIG. 69.4 A 15-month-old boy with a week of irritability who presents with a generalized tonic-clonic seizure followed by sleepiness with extensive thrombosis of the inferior sagittal sinus, straight sinus, internal cerebral veins, and vein of Galen. Laboratory studies showed severe iron deficiency (hemoglobin 6.2 g/dL, microcytic anemia, and high total iron-binding capacity). There is symmetric T2 hyperintensity within the bilateral thalami associated with involvement of the deep venous system.

Both UFH and LMWH are recommended in adults with CSVT.[59] With close monitoring, UFH and LMWH can be administered to children, and this likely improves outcome.[60-63] Recommendation from the International Paediatric Stroke Study (IPSS) group is that older children without hemorrhage should receive anticoagulation. In a single-center study, worse clinical outcome and propagation of thrombus were associated with a lack of anticoagulation. Hemorrhagic complications were relatively rare (5%); however, children with "significant intracranial hemorrhage" were excluded from anticoagulation treatment[62] (Table 69.6).

TABLE 69.6

Guideline for Anticoagulation in Cerebral Sinus Venous Thrombosis

Guideline	Population	Recommendation
American College of Chest Physicians (ACCP) guidelines, 2012[15]	Children	Initial UFH or LMWH, then LMWH or vitamin K antagonist for minimum 3 months plus another 3 months if occlusion persists or symptoms ongoing. For children with CSVT with significant hemorrhage, anticoagulation as above or follow-up neuroimaging at 5-7 days and anticoagulation if thrombus propagation has occurred.
American Heart Association Guidelines for Management of Stroke in Infants and Children, 2008[45]	Children	Consider initial UFH or LMWH followed by warfarin for 3-6 months, whether or not intracranial hemorrhage is present.
Diagnosis and Management of Cerebral Venous Thrombosis, AHA, 2011[59]	Adults	Initial UFH or LMWH in full anticoagulant doses is reasonable, followed by vitamin K antagonists, regardless of the presence of ICH. With provoked CSVT, vitamin K antagonists may be continued for 3-6 months. With unprovoked CVT, vitamin K antagonists may be continued for 6-12 months.

Thrombolysis, thrombectomy, or surgical decompression may be considered in children with severe CSVT in whom there is no improvement with UFH.[15] Studies of thrombolysis and thrombectomy for CSVT have not been performed but case reports and series exist, particularly of children who are comatose or have declining mental status.[55,64]

Many patients with CSVT have increased intracranial pressure and are at risk for vision loss.[53] Lumbar puncture is the most effective way to lower ICP; however, this option requires interruption of anticoagulation to decrease the risk of bleeding.

Prognosis

The mortality following CSVT in childhood is approximately 4% to 7%,[51,65] and CSVT is frequently associated with long-term neurologic sequelae.[66] Recurrence has been reported in 6% of children following CSVT at an average follow-up of 36 months. Predictors of recurrence included persistent occlusion from CSVT, presence of heterozygosity for G20210A mutation, lack of anticoagulant therapy, and initial thrombosis occurring after 2 years of age.[60]

Vision loss can occur due to elevated ICP after CSVT,[53] and accordingly ophthalmology follow-up is warranted. Children with ongoing thrombophilia are at increased risk of recurrent pathologic thrombosis, particularly with triggers such as immobilization, pregnancy and puerperium, prolonged plane travel, and oral contraceptive use; preventive precautions should be discussed with the patient and family. Recurrent thrombosis can occur in the absence of identified thrombophilia as well.[60]

Spontaneous Intracranial Hemorrhage

Although spontaneous ICH, or hemorrhagic stroke, accounts for less than 20% of strokes in adults, it accounts for almost half of all pediatric stroke.[67-69] Spontaneous ICH includes intraparenchymal hemorrhage accounting for approximately 75% of cases,[68] intraventricular hemorrhage (IVH), and subarachnoid hemorrhage (SAH) of nontraumatic origin. Following ICH, approximately 10% to 25% of children will die,[70,71] and over 70% will have neurologic deficits.[72]

The three most common vascular malformations of the CNS are arteriovenous malformations (AVMs), cerebral cavernous malformations (CMs), and venous malformations. AVMs account for approximately half of intraparenchymal ICH.[64,67] CMs account for approximately one-quarter of ICH, with higher numbers found in later studies that included MRI assessment. Other vascular malformations, brain tumors, and coagulation defects (thrombocytopenia, hemophilia, hepatic failure, anticoagulation) account for most of the remaining cases of spontaneous ICH in childhood.

Arteriovenous Malformations

AVMs are abnormal tangles of vessels (Fig. 69.5) that connect arteries directly to veins, resulting in abnormally high flow and pressures in vessels with weak walls. This disrupts normal blood flow and leads to hemorrhage and the formation of aneurysms. Eighty percent of AVMs are supratentorial, and three-quarters of those that become symptomatic present with ICH. Children with ruptured AVMs present with altered mental status including coma and seizures. Multiple AVMs are more common in children than adults and suggest hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu),[73] familial AVMs, and Wyburn-Mason syndrome. Vein of Galen malformation is a distinct AVM that appears in newborns and is associated with congestive heart failure due to left-to-right cardiovascular shunting.

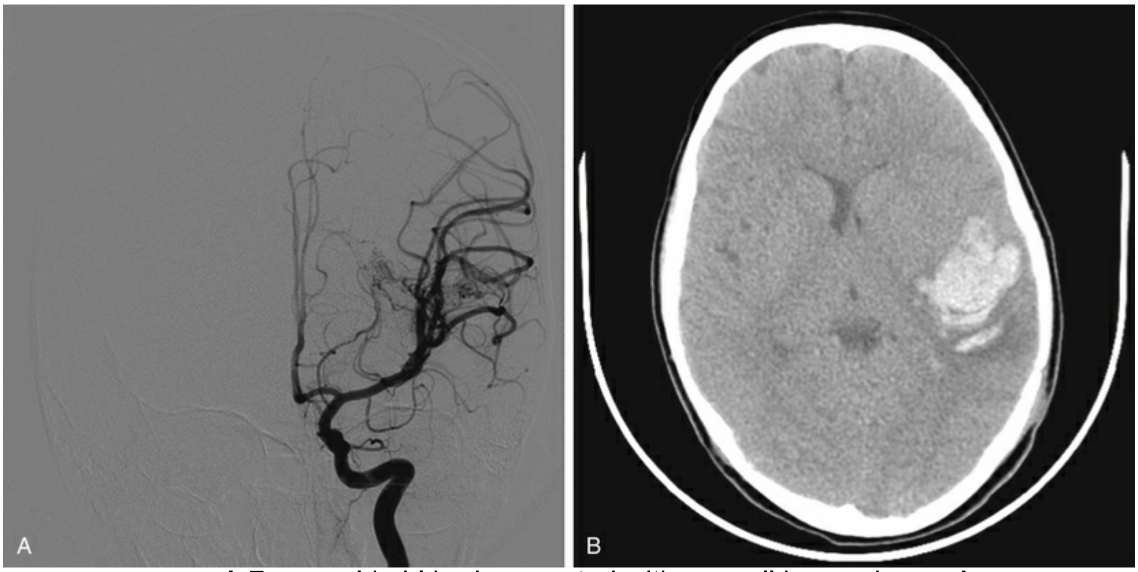

FIG. 69.5 A 7-year-old girl had presented with a small hemorrhage. A sylvian fissure AVM is seen on left carotid injection during conventional cerebral angiogram (A). Head CT shows a large hemorrhage requiring emergent evacuation 1 month following the initial angiogram (B). A small residual was treated with radiosurgery, and the lesion is obliterated at 10-year follow-up.

The risk of hemorrhage in children with known AVMs is 2% to 4% per year, and 25% of the hemorrhages are fatal.[74-76] Although children have a lower annual risk of hemorrhage than adults, they have a greater lifetime risk. Although AVMs are traditionally considered to be congenital without the potential for growth, recurrence of AVM has been reported in children following complete obliteration, and long-term follow-up is indicated.[77] Larger AVMs may be less likely to hemorrhage than small AVMs, perhaps because of increased pressure in the smaller malformations.[78-80] As AVMs are often diagnosed at the time of hemorrhage, there may be a bias toward diagnosis of lesions with a higher incidence of hemorrhage. The incidentally found AVM may have a different natural history, but there are insufficient data to make this determination.[81]

MRI will demonstrate AVMs, and cerebral catheter angiograms will establish the arteriovenous shunt, as well as feed arteries and drain veins. The Spetzler-Martin grading system accounts for size, involvement of eloquent brain, and pattern of venous drainage.[82] AVMs under 3 cm in maximal diameter, with superficial drainage and away from critical areas (eg, language, motor, and visual areas), have the lowest risk associated with intervention and the best overall prognosis (Table 69.7). When possible, AVMs should be treated with total surgical resection. The annual risk of rebleeding following AVM hemorrhage is 20% in children, approximately fourfold the risk in adults.[83] Deep-seated AVMs and AVMs with a recent (5-year) history of hemorrhage are at higher risk of bleeding.[81] Surgical treatment is associated with a very high success rate but is not universally curative. A series[84] of pediatric AVMs resected surgically found about a 1% recurrence at 5 years suggesting some degree of postoperative surveillance is warranted.

TABLE 69.7

Spetzler-Martin Grading Scale for Arteriovenous Malformations

Size 0-3 cm: 0 points
Size 3-6 cm: 1point
>6 cm: 2 points
Eloquent (yes = 1, no = 0)
Deep drainage (yes = 1, superficial only = 0)
Grades 1-3 generally considered operative

Partial treatment with embolization does not decrease risk of hemorrhage.[85] Complete obliteration with embolization is not possible, but embolization has been used as an option to reduce the size prior to surgical resection or radiosurgery. Gamma knife has been used to treat pediatric AVM with an obliteration rate of 71.3% after one treatment and 62.5% for patients requiring another treatment. The mean time to obliteration was 32.4 and 79.6 months, respectively.[86] AVMs with a nidus diameter less than 2.5 cm and with a single draining vein were most likely to respond completely to radiosurgery,[87] but these same characteristics also predispose to a favorable outcome with microsurgical resection. Ischemic changes presenting as clinical stroke at the site of radiation can occur following radiation.

Aneurysms

Aneurysms account for 10% of hemorrhagic strokes in childhood[88] and usually have symptomatic onset in children younger than 2 years or older than 10 years of age.[89] Ruptured aneurysms usually present with SAH but can present with IVH or intraparenchymal hemorrhage. The most common location for aneurysm in children is a saccular aneurysm at the internal carotid artery bifurcation followed by the middle cerebral artery bifurcation.[90] Infants and children are more likely than adults to have giant aneurysms and posterior circulation involvement, and they are less likely to have aneurysms of the anterior communicating artery and posterior communicating artery,[91] although most giant aneurysms in infants involve the middle cerebral artery.[92] Approximately 5% of children with aneurysms have multiple aneurysms, as opposed to 20% in adults.

There are multiple genetic disorders associated with the development of aneurysms, including coarctation of the aorta,[93,94] fibromuscular dysplasia,[95,96] Ehlers-Danlos syndrome,[97] pseudoxanthoma elasticum,[98] autosomal dominant polycystic kidney disease, and a family history of aneurysms. Aneurysms can also be associated with AVMs[99,100] and can form following radiation for pediatric brain tumors and AVMs.

Intracerebral locations, as opposed to SAH, suggest an aneurysm due to infection, or mycotic aneurysms. Infective endocarditis, meningitis, chronic pulmonary infection, and intravenous drug use are commonly predisposing infections. Mycotic aneurysms tend to be more distal and are often multiple.

Cerebral catheter angiography is the study of choice for cerebral aneurysms, although CTA is often the initial imaging study performed with head CT on presentation, and it may be useful in emergency situations when urgent operative decompression of the hemorrhage is needed. Head MRI and MRA can be used for screening of aneurysms but are less sensitive than angiography, which provides more detail of the vascular anatomy.[101] Cerebral catheter angiography can be diagnostic and preparatory for endovascular treatment as well.

The annual risk of aneurysmal rupture is estimated at 0.1% to 8%, with larger aneurysms at higher risk. In patients with unruptured aneurysm, symptoms can be related to expanding size. Common symptoms include third nerve palsy, afferent

pupillary defect, and other cranial nerve deficits, depending on the location of the aneurysm.

Frank rupture of an aneurysm results in catastrophic ICH, with sudden severe headache, altered mental status, nausea and vomiting, and loss of consciousness. The mortality rate in children following aneurysmal rupture is 20%.[102] Some patients will have a recent history of *sentinel bleed* with a severe headache. The sudden onset of severe headache requires a neuroimaging evaluation for possible SAH. The most common complication following SAH is cerebral vasospasm resulting in ischemic stroke. Vasospasm usually presents within 5 to 10 days following the hemorrhage but can present for up to 2 weeks. In adults, euvolemia and nimodipine, a calcium channel blocker, are recommended following aneurysmal SAH to prevent delayed cerebral ischemia, with induction of hypertension if delayed cerebral ischemia has occurred.[103] Nimodipine and Pravachol have been used together to prevent or minimize vasospasm. Hypervolemia using intravenous fluids has not been shown to be effective in preventing vasospasm, and currently maintaining patients in a euvolemic state is recommended, with hypovolemia carefully avoided. Hypertension may be useful in treating symptomatic vasospasm. Approximately one-third of patients will exhibit cerebral salt wasting and as such, serum sodium should be monitored. Hydrocephalus is common and CSF diversion often necessary.

As recurrent hemorrhage from a ruptured aneurysm is a frequent and early event, with 15% of adults suffering a recurrent hemorrhage in the first 24 hours,[104] treatment of the aneurysm must be prompt. Options for treatment include endovascular therapy, ligation, and clip placement. Long-term follow-up is indicated, as over 40% of children with aneurysms will develop new aneurysms later in life.[105] For adults, the 10-year risk of SAH in a patient with one first-degree relative with SAH was 0.8%, and with two first-degree relatives the risk was 7.1%.[106] The risk to other family members of children with nonsyndromic aneurysms is unknown.

Cavernous Malformations

Cerebral CMs are vascular malformations with thin-walled sinusoidal spaces lined with endothelial tissue without intervening parenchyma, often containing calcifications. CMs cause approximately one-fifth of ICH in childhood.[67,107] For untreated CMs, the risk of recurrent hemorrhage is 4% to 5% per year. CMs occur in approximately 1 in 200 adults and account for approximately 10% of vascular malformations of the CNS. Most occur in the brain, usually supratentorially, although infratentorial and brain stem involvement can occur. Less frequently, the spinal cord is involved. There is no arteriovenous shunting, so the degree of hemorrhage tends to be smaller than with AVMs, often with hemosiderin staining in the absence of a clinical hemorrhage.

Most CMs are asymptomatic with 20% to 30% of patients having symptoms. CM can present with headache, seizures, focal neurologic deficit, and hemorrhage. Seizures are the most common presenting symptom, especially with involvement of the frontal and temporal lobes (Fig. 69.6). CMs often increase in size over time, with a progressing and regressing course due to resorption of blood and reorganization followed by recurrent hemorrhage. Although CMs are low-flow lesions, severe hemorrhage can occur. One study of patients age 25 years and younger found that the hemorrhage rate was 1.6% per patient-year and 0.9% per cavernoma-year. The

hemorrhage rate in the symptomatic group was 8% annually and 0.2% in the asymptomatic group where CM was found incidentally.[108] In a series of 292 patients diagnosed at age 3.5 to 88.9 years (mean 45.8 years), 74 presented with hemorrhage. The annual risk of hemorrhage in patients presenting with hemorrhage was 6.2%, with risk decreasing over time. The risk of hemorrhage increased in the setting of multiple CMs.[109]

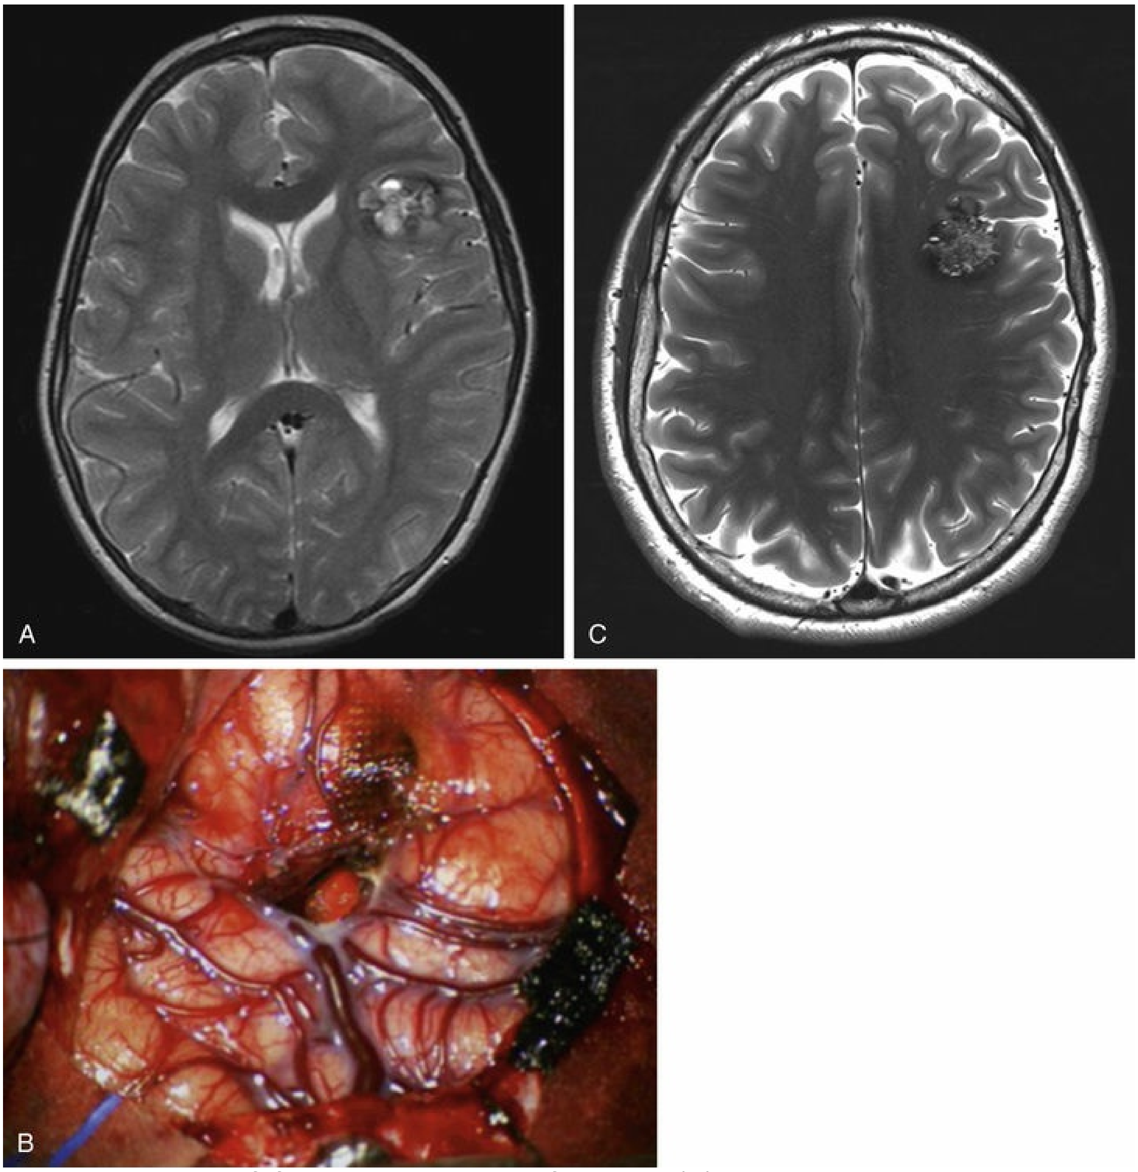

FIG. 69.6 A left frontal cavernous malformation (A) was resected in an 8-year-old with intractable focal motor seizures, resulting in 10 years of seizure freedom. The lesion was entered from within the sulcus (B). Seizures recurred in the setting of a new lesion superior to the first (C) along with a new lesion in the right cerebellum (not shown).

CM can be either familial or sporadic, and the incidence of CM on imaging increases during childhood with age. Multiple CMs occur in 13% of sporadic cases and half of familial cases,[110] with greater number of lesions predicting familial CM. Multiple genetic mutations have been associated with familial CM, including

CCM1/KRIT1, CCM2/MGC4607, and CCM3/PDCD10, accounting for three-fourths or more of families.[111] In one series of 92 children with CM, 30% had multiple CMs and 9% had a family history of CMs. [108] In another series of 66 children with CM, 7 (11%) had multiple CMs. [112]

On MRI, CMs are described as having a popcorn appearance due to the mixture of high and low T1 and T2 signal surrounded by hemosiderin from chronic, recurrent hemorrhage. Findings on CT are nonspecific, and CMs are not detectable on catheter angiography. CMs can be associated with the developmental venous anomalies that are seen on angiography, however.

If complete resection of a particular CM lesion is possible, this is curative. Most patients with symptomatic localization epilepsy associated with the CM will be seizure free following resection as well, especially if the associated hemosiderin rim is also removed (see Fig. 69.5). Functional considerations may limit surgery or define the surgical approach. Preoperative assessment may include functional MRI or other mapping tools if the location is suspected to be near the motor or language cortex. Such mapping tools are possible in patients as young as age 5 or 6 years.[113]

Resection is not always an option and can be associated with increased neurologic deficit. Brain stem CMs in childhood are particularly problematic, as they tend to be larger with a higher rate of recurrence following incomplete resection than seen in adults.[114] Radiosurgery has been considered for patients in whom surgery is not an option. Radiosurgery does not appear to be curative and can be associated with significant complications. The adaptation of stereotactic laser ablation has also been applied to the treatment of CMs, though the experience with this approach is extremely limited to date.[115]

The risk of intervention needs to be balanced against the risk with natural history. A posterior fossa CM is associated with a greater risk of hemorrhage, as well as rebleeding, than other locations. Brain stem CMs are high risk if untreated, although surgical resection is also high risk in this location, often requiring skull base approaches to access the lesion where it comes to the surface. Surgical management of patients with multiple lesions, particular familial CM where lesions may be numerous, is possible if the symptomatic lesion is identified and resectable. In these cases, risk of recurrence, or of a new lesion arising in adjacent or distant areas, is possible (see Fig. 69.6C).

Genetic screening for patients with familial CM has been debated and currently identified genes account for 96% of familial cases. Nevertheless, if a causative gene is found in a pedigree, this could be used to screen other family members. Family members of patients with CM should be imaged if there are any symptoms causing a concern for CM such as headache, seizures, or neurologic deficit.

Symptomatic epilepsy will need appropriate antiepileptic treatment. Seizures may be medically refractory or intractable. Follow-up MR imaging should be pursued every 1 to 2 years to assess for growth or hemorrhage of the CM.

Coagulation Disorders

Hemophilia A and B can result in spontaneous ICH, as can severe thrombocytopenia and coagulopathy due to liver failure. ICH associated with vitamin K deficiency occurs in infants who do not receive vitamin K prophylaxis at birth due to omission or parental choice.[116] Late ICH associated with vitamin K deficiency peaks at 3 to 8

weeks and can be catastrophic.[117]

General Care of the Child With Intracerebral Hemorrhage

A child with ICH can present with emesis, severe headache, seizures, and declining mental status, and children with ICH can deteriorate rapidly to coma and death. Rapid diagnosis and stabilization of the child with ICH is critical. Head CT can detect ICH as well as mass effect and impending herniation. A CBC, coagulation profile and type and hold or cross should be sent. Initial stabilization will include ensuring control of the airway and ventilation, treatment of seizures with antiepileptic drugs, and prevention of fever. Specific coagulopathy should be identified and corrected.

Urgent evacuation of hemorrhage may be indicated, as well as decompressive hemicraniectomy. Management of elevated ICP may include hyperosmolar therapy such as mannitol or hypertonic saline, hyperventilation for induced hypocapnia and cerebral vasoconstriction, and elevation of the head of the bed up to 30 degrees. A ventriculostomy drain allows drainage of CSF as well as ICP monitoring and is indicated in the setting of obstructive hydrocephalus as a consequence of IVH.

Prognosis

Prognosis following ICH depends on the etiology and severity of the initial hemorrhage, risk of recurrence, and morbidity associated with treatment of the underlying lesion. A study of 56 children followed for a mean of a decade after ICH found that 13 children died acutely, 9 suffered recurrent hemorrhage (which was fatal in 3 children), and only a quarter of the survivors were without neurologic or cognitive deficit.[118]

Conclusion

Childhood stroke, including AIS, CSVT, and ICH, is a significant cause of childhood morbidity and mortality. Children presenting with acute stroke require intensive care to address urgent management, supportive care, neuroprotection, and prevention of early recurrence and complications.

CHAPTER 70

Central Nervous System Infections and Related Conditions

Erin P. Reade, Dennis W. Simon, Mark E. Rowin

PEARLS

- Despite the success of vaccination for common bacterial meningitis pathogens, intensivists must continue to look for and treat both vaccine and nonvaccine serotypes of *S. pneumoniae* and Neisseria.
- Viral meningitis is a diverse disease process with a broad range of presentations and outcomes and little specific therapy.
- Inflammatory and autoimmune causes of CNS disease are emerging as important entities in the pediatric ICU and require a high index of suspicion.

Introduction

Infections of the central nervous system (CNS) and other conditions that often mimic CNS infections are life-threatening indications for admission to the pediatric intensive care unit (PICU). The diversity of infectious agents causing CNS disease includes bacteria, viruses, fungi, parasites, and amebas. In addition, posttraumatic and postsurgical infections, though relatively uncommon, can be fatal. Inflammatory diseases such as acute disseminated encephalomyelitis (ADEM) and autoimmune processes such as acute hemorrhagic leukoencephalitis, anti–N-methyl-D-aspartate (NMDA) receptor-mediated encephalitis, and CNS hemophagocytic lymphohistiocytosis (HLH) feature diverse presentations and require a high index of suspicion. The pediatric intensivist must integrate knowledge of epidemiology, signs and symptoms, predisposing factors, and host defenses as well as utilize appropriate cerebrospinal fluid analysis, pathology, and imaging in order to diagnose and treat CNS infections and related diseases.

Bacterial Meningitis

Acute bacterial meningitis is a relatively common and potentially severe infection in children. Bacterial meningitis often results from the hematogenous dissemination of microorganisms from a distant site of infection. More than two-thirds of cases of meningitis occur in the first 2 years of life, owing in part to an immature immune system and developmental differences in the vascularity of the brain. These children are often admitted to a PICU for supportive care.

Many microorganisms have the ability to cause meningitis. Most are acquired through a hematogenous route, others through direct extension from nasal cavities, paranasal sinuses, mastoids, or the middle ear. CNS infections can also be associated with trauma, surgery, and placement of foreign materials.

Epidemiology

The epidemiology of bacterial meningitis continues to shift with the development of conjugate vaccines for the most common bacterial pathogens. In the 1980s, five etiologic agents, namely *Haemophilus influenzae, Neisseria meningitidis, Streptococcus pneumoniae, Listeria monocytogenes,* and *Streptococcus agalactiae,* accounted for almost 80% of meningitis cases in the United States. A conjugate vaccine against *Haemophilus influenzae* type b (Hib) was introduced in the early1990s. During the first decade of the 21st century, a pivotal change occurred in the management of acute bacterial meningitis with the introduction of the conjugate vaccines for *S. pneumoniae* (Prevnar) in 2000 and *N. meningitidis* (Menactra) in 2005. These bacterial conjugate vaccines have dramatically altered the epidemiology of childhood meningitis, with viral agents now becoming increasingly predominant. In addition, nonvaccine serotypes have emerged as "newly recognized" pathogens.[1,2] The isolation of nonvaccine serotypes of *S. pneumoniae* has increased since the introduction of the conjugate vaccine. Of great therapeutic concern, approximately one-quarter of these invasive isolates were penicillin-resistant, and more than 10% were resistant to cephalosporins.

The introduction of vaccines against *Haemophilus, Pneumococcus,* and *Neisseria* has had an undeniable impact on the incidence and etiology of meningitis. A study using the Kids' Inpatient Database and the National Inpatient Database examined trends in bacterial meningitis over the 19 years since routine vaccinations against these organisms were instituted in the United States.[3] Over this period, the authors noted approximately 15,000 cases per year. However, there has been a 47% reduction in cases of meningitis in children (and elderly patients) since the introduction of the conjugate vaccines. When all ages are considered, the incidence of both pneumococcal and meningococcal meningitis decreased by ~10%. However, during this same period, an increase in the incidence of staphylococcal and streptococcal meningitides was observed.

S. pneumoniae continues to be a leading cause of bacterial meningitis both internationally and in the United States. In a study of children presenting to the emergency department with bacterial meningitis, roughly one-third of cases were caused by *S. pneumoniae*. Of interest, 62% of the pneumococcal isolates were nonvaccine serotypes.[4] An epidemiologic study from the United States showed the incidence of *S. pneumoniae* meningitis fell from 0.8 per 100,000 people in 1997 to 0.3

per 100,000 people in 2010. Among infants younger than 1 year of age, the incidence is even less, estimated at 0.2 per 100,000. The case mortality from pneumococcal meningitis decreased from 0.049 per 100,000 people in 2004 to 0.024 per 100,000 people in 2008.[5]

Neisseria meningitidis is the second most common cause of sepsis and meningitis beyond the neonatal period.[5] Following the introduction of the conjugated meningococcal vaccine, the incidence of *Neisseria meningitidis* meningitis decreased from 0.7 per 100,000 people in 1997 to 0.1 per 100,000 people in 2010. Globally, *Neisseria meningitidis* causes around 500,000 cases of meningitis and septic shock every year, although incidence rates vary from <1 per 100,000 per year in North America to 10 to 1000 per 100,000 per year in sub-Saharan Africa. The peak incidence of invasive meningococcal disease occurs in children between 6 months and 2 years of age, with a second smaller peak in adolescents and young adults. Capsular group B is the major disease-causing group in most countries and causes the highest rates of disease in North America and Europe. In a 9-year Canadian study of invasive meningococcal disease, the authors noted that this organism presented as meningitis in over 50% of cases and, in children, had a case fatality rate of 2%.[6]

During the first months of life, *Escherichia coli* and other gram-negative organisms cause one-fifth of sepsis and meningitis cases. Because of targeted intrapartum antibiotic prophylaxis, *Streptococcus agalactiae* (group B streptococcus) meningitis is increasingly less common in newborns in the United States.[7,8] However, in a study from the United Kingdom evaluating the epidemiology of meningitis in children in the postvaccine age, group B streptococcus was the most frequently identified bacterial pathogen.[9] Additionally, a bacterial pathogen was detected in only 19% of children with meningitis. A virus was identified in 37% of cases, with enterovirus as the most common viral pathogen identified. In greater than 40% of cases, no pathogen was identified.

Mycobacterium tuberculosis is a rare cause of pediatric meningitis, but it is well recognized for its high degree of morbidity and mortality. Tuberculous (TB) meningitis disproportionately affects young children and, after scrofula, is the most common form of childhood extrapulmonary tuberculosis. Before antituberculosis drugs, TB meningitis invariably caused death, usually within weeks. One meta-analysis showed that risk of death from TB meningitis was 19.3%, and risk of neurologic sequelae among survivors was greater than 50%.[10] As with acute bacterial meningitis, later diagnosis in TB meningitis is associated with poorer outcomes. Morbidity and mortality have improved with effective antimicrobials, corticosteroid use, and advances in management of intracranial hypertension. However, early diagnosis remains a substantial challenge because stage 1 (the earliest stage of TB meningitis) presents with nonspecific signs and symptoms.

Pathogenesis

Tissue injury and subsequent morbidity in acute bacterial meningitis is caused by multiple factors including bacterial proliferation in the subarachnoid space, release of bacterial products, local immune response from CNS tissue, and leukocyte migration into infected tissue. Colonization of the nasopharynx is frequently the antecedent event in clinical meningitis. Organisms in the nasopharynx penetrate respiratory epithelial cells as a preamble to disease. Organisms then enter the

bloodstream and undergo intravascular multiplication and eventually penetrate the blood-brain barrier (BBB). A lack of immune defenses in the subarachnoid space allows for the rapid multiplication of bacteria within the CNS.

Certain predisposing factors are clearly associated with increased risk for development of acute bacterial meningitis. Children with asplenia, humoral immunodeficiencies, cochlear implants, human immunodeficiency virus, and cerebrospinal fluid (CSF) leakage secondary to trauma are at increased risk for pneumococcal meningitis. Asplenic children and those with complement deficiencies are at increased risk for meningococcal meningitis. On rare occasions, otitis media has been associated with *Streptococcus pyogenes* meningitis.[11] Infections by *Staphylococcus aureus* and coagulase-negative staphylococci are generally associated with neurosurgery or trauma. Many studies have explored the genetic determinants of infectious diseases. In invasive meningococcal disease, several mutations and polymorphisms have been associated with a higher susceptibility and severity of illness. To date, the genetic markers with the strongest supportive evidence are specific polymorphisms in the coding genes of plasminogen activator inhibitor 1 (PAI-1) and receptors of the Fc fraction of immunoglobulins.[12]

Clinical Manifestations

The classic clinical presentation of meningitis is characterized by fever, headache, nuchal rigidity, and altered mental status. Clinical symptoms are often ambiguous in the pediatric patient. In fact, the triad of fever, neck stiffness, and a change in mental status is present in less than 50% of pediatric cases. Nuchal rigidity is frequently absent, and changes in mental status such as irritability can often be dismissed as normal behavior in a newborn. Similarly, Kernig and Brudzinski signs frequently go unrecognized or are absent. The presence of petechiae and purpura may suggest meningococcus as the causative agent. However, similar findings have been observed in children with *S. pneumoniae* and *H. influenzae* type a sepsis.[13] A meta-analysis evaluating clinical prediction rules for meningitis showed that no constellation of clinical signs and symptoms was 100% predictive of meningitis.[14] Thus the clinician must have a high index of suspicion when considering this diagnosis in pediatric patients.

Poorly reactive pupils, a bulging fontanel, diplopia, papilledema, and uncontrollable vomiting are signs of increased intracranial pressure (ICP). Elevated ICP is frequently noted in bacterial meningitis, most likely due to obstruction of the arachnoid tissue by leukocyte migration, as a consequence of CNS inflammation or obstruction of CSF flow by purulent debris of the lateral, third, or fourth ventricles. However, frank hydrocephalus visible on computed tomography (CT) of the brain is rare.

A multiyear retrospective study from South America evaluated risk factors in pediatric patients with confirmed bacterial meningitis for the subsequent development of seizure activity. Risk factors for seizure development included age less than 2 years, pneumococcal etiology, altered mental status at admission, and CSF leukocyte count less than 1000 cells. Generalized seizures were present in 20% to 30% of patients within the first 3 days of illness. The presence of focal seizures and onset past the third day of illness were associated with long-term neurologic sequelae. Development of seizure activity in these patients was associated with a

ninefold increase in mortality.[15]

Diagnosis

Meningitis is a serious medical emergency in which the microbiology laboratory plays a critical role in early identification of the causative bacterium. When clinically feasible, the diagnosis of meningitis requires the examination of CSF. In most cases of bacterial meningitis, the diagnosis relies on the isolation of bacteria from a CSF specimen. Cell count and differential, protein, glucose, Gram stain, and cultures are essential tests to be performed. In bacterial meningitis, about 80% of patients will have concurrent bacteremia, but the use of blood culture alone as an initial screening test is not appropriate. Prior oral antimicrobial therapy will not significantly alter CSF cell counts, differential, and chemistries in children with bacterial meningitis. However, Gram stain and culture sensitivity are greatly reduced.[16]

Lumbar puncture should be postponed in children with an ongoing coagulopathy, concern for elevated ICP (such as altered mental status or hydrocephalus seen on CT or MRI), cardiorespiratory difficulty, and patients with suspected mass-occupying lesions. Although not required in all children with suspected meningitis, CT scan is indicated prior to lumbar puncture in those with focal neurologic findings or signs of elevated ICP. It is important to remember that even when CT scans are normal, herniation may still occur in both children[17] and adults with meningitis.[18]

Antibiotic therapy and other supportive measures must be started early when meningitis is suspected and should not be delayed while awaiting CSF results. Delays in antibiotic administration have been repeatedly shown to increase mortality. A delay of antibiotics initiation for as little as 3 hours can be associated with an unfavorable outcome. The risk for poor outcome increases by up to 30% per hour of antibiotic treatment delay.[19] Routine end-of-treatment lumbar punctures are no longer recommended. However, meningitis caused by multidrug resistant *S. pneumoniae* or gram-negative bacilli meningitis may require a repeat lumbar puncture at 48 hours after initiating therapy to document sterilization.

CSF with pleocytosis, usually greater than 1000/uL, and a predominance of polymorphonuclear leukocytes (PMN) is highly suggestive of bacterial meningitis. High protein and low glucose (usually $< \frac{1}{2}$ serum value) concentrations also support the diagnosis. A predominance of lymphocytes and monocytes suggests a viral pathogen. These can also be observed in patients with rickettsial and tuberculous meningitis. CSF eosinophils are commonly observed in patients with CSF shunt devices, but also this can be observed in parasitic CNS infections such as baylisascariasis and *Angiostrongylus* species.

Clinicians must remember that a PMN-predominance may be observed early in enteroviral meningitis as well. Frequently, these patients have normal protein and glucose concentrations. Interestingly, hypoglycorrachia can be observed with certain viral pathogens such as enterovirus and mumps virus. On occasion, a small percentage of patients may have an initial “normal-appearing” CSF analysis, especially with *N. meningitidis*.

Positive CSF cultures remain the gold standard of meningitis diagnosis. Gram stains have been reported to demonstrate organisms in 50% to 75% of patients with bacterial meningitis. The clinician must be cautioned not to make significant changes in antimicrobial therapy solely based on a Gram stain result, as this may reflect

difference in CSF staining during slide preparation. Routine use of rapid bacterial antigen detection assays has been shown to be of limited clinical relevance.[20] In children, the combination of CSF gram staining and latex agglutination studies can detect 85% of cases of acute bacterial meningitis. However, the addition of CSF cultures to Gram stains and latex agglutination studies increases the sensitivity and specificity of meningitis detection to almost 100%.[21]

Antibiotic pretreatment often results in a clinical dilemma, related to identification of the pathogen causing meningitis. However, several new laboratory tools are now available to pediatric intensivists. A multicenter study from Asia and Africa demonstrated high sensitivity and specificity for immunochromatographic analysis of pneumococcal antigen.[22] Similarly, real-time fluorescent quantitative polymerase chain reaction (PCR) amplification of the bacterial 16S rRNA gene is a useful clinical tool for the rapid diagnosis of bacterial meningitis. Compared to bacterial culture controls, sensitivity for *S. pneumoniae* and *N. meningitidis* as the etiologic agents was 86% to 100%.[23-25] In a clinical setting, a real-time PCR for *N. meningitidis* was found to have high sensitivity, specificity, and predictive values.[26] Serum procalcitonin assays have been used to differentiate between bacterial and aseptic meningitis. In a small study, procalcitonin determination had 99% sensitivity and 83% specificity for distinguishing bacterial meningitis from other causes.[27] Additional clinical studies will be needed to assess the ultimate clinical roles for these assays.

Treatment

An effective antimicrobial agent for the treatment of bacterial meningitis must be bactericidal and must achieve high concentrations in the CSF. In addition, initial empiric therapy should take into consideration antimicrobial resistance among the most likely meningeal pathogens. Hospital antibiograms that demonstrate resistance among local community flora are an invaluable resource. Once meningitis is suspected, antimicrobial therapy must be initiated promptly.

All critical care clinicians should be familiar with recommendations for antibiotic management in bacterial meningitis.[28] Tables 70.1 through 70.3 provide a listing of most frequent meningeal pathogens and recommended antimicrobial regimens along with dosage information. The Infectious Disease Society of America and the British National Institute for Clinical Evidence have both published guidelines on duration of therapy for bacterial meningitis in children. These recommendations are similar but not identical (Table 70.4). Guidelines such as these are useful tools in pediatrics. However, the emphasis on fixed durations of IV antibiotics needs to take into account the patient's clinical response. Studies suggest that the currently established length of antibiotic therapies for meningitis may soon be redefined.[29]

TABLE 70.1

Initial Antimicrobial Therapy for Bacterial Meningitis Based on Presumptive Pathogen(s)

Age or Predisposing Condition	Likely Pathogens	Antimicrobial Therapy
<1 month	*Escherichia coli*, *Streptococcus agalactiae*, *Klebsiella* species, *Listeria monocytogenes*	Ampicillin plus cefotaxime +/− aminoglycoside

1-2 months	*Streptococcus pneumoniae, Neisseria meningitidis, Streptococcus agalactiae, Haemophilus influenzae, Escherichia coli*	Vancomycin plus third-generation cephalosporin[a]
2 months to 5 years	*Streptococcus pneumoniae, Neisseria meningitidis, Haemophilus influenzae*	Vancomycin plus third-generation cephalosporin[a]
>5 years	*Streptococcus pneumoniae, Neisseria meningitidis*	Vancomycin plus third-generation cephalosporin[a]
Humoral immunodeficiency, HIV, asplenia	*Streptococcus pneumoniae, Neisseria meningitidis, Haemophilus influenzae, Salmonella* species	Vancomycin plus third-generation cephalosporin[a]
Complement deficiencies	*Neisseria meningitidis, Streptococcus pneumoniae*	Vancomycin plus third-generation cephalosporin[a]
Basilar skull fractures	*Streptococcus pneumoniae, Neisseria meningitidis, Streptococcus pyogenes*	Vancomycin plus third-generation cephalosporin[b]
Cerebrospinal fluid shunt related	Coagulase-negative staphylococci, *Staphylococcus aureus, Pseudomonas aeruginosa, Propionibacterium acnes*	Vancomycin plus ceftazidime or vancomycin plus cefepime or vancomycin plus meropenem[b]
Cochlear implants	*Streptococcus pneumoniae*	Vancomycin plus third-generation cephalosporin[a]

[a]Cefotaxime or ceftriaxone.

[b]The choice of anti–gram-negative bacillary agent should be based on the institution's susceptibility patterns.

TABLE 70.2

Antimicrobial Therapy for Specific Meningeal Pathogens

Streptococcus agalactiae	Penicillin G +/− gentamicin or ampicillin +/− gentamicin
Haemophilus influenzae, β-lactamase-negative	Ampicillin
H. influenzae, β-lactamase-positive	Third-generation cephalosporin[a]
Streptococcus pneumoniae, penicillin-susceptible	Penicillin G or ampicillin
S. pneumoniae, penicillin-resistant, cephalosporin-susceptible	Third-generation cephalosporin[a]
S. pneumoniae, drug-resistant (multiply-resistant)	Vancomycin plus rifampin
Neisseria meningitidis	Third-generation cephalosporin[a]
Neisseria meningitidis, penicillin-susceptible	Penicillin G or ampicillin
Escherichia coli Other aerobic enteric gram-negative bacilli (not including *Pseudomonas aeruginosa*)	Cefotaxime or ceftriaxone (if >1 month of age) plus aminoglycoside
Pseudomonas aeruginosa	Meropenem plus aminoglycoside or cefepime plus aminoglycoside or ceftazidime plus aminoglycoside
Coagulase-negative staphylococci, methicillin-resistant *Staphylococcus aureus*	Vancomycin +/− rifampin
Methicillin-susceptible *S. aureus*	Nafcillin

[a]Cefotaxime or ceftriaxone.

TABLE 70.3

Dosages of Antimicrobial Agents for Treatment of Bacterial Meningitis Expressed as mg/kg/day[a]

Antibiotic	Neonates 0 to 7 days > 2000 grams[b]	Neonates > 7 days > 2000 grams	Infants and Children	Maximum Daily Adult Dose
Ampicillin	150	200	300-400	12 grams
Cefepime	-	-	150	6 grams
Cefotaxime	150	200	200-300	12 grams
Ceftriaxone	-	-	100	4 grams
Gentamicin	5	7.5	7.5	5 mg/kg
Meropenem	-	-	120	6 grams

Penicillin G	150,000	200,000	300,000	24 million units
Rifampin	-	10-20	10-20	600 mg
Vancomycin	30	45	60	45 mg/kg

[a]Exception: Penicillin G is expressed as units/kg/day.

[b]Dosages of agents for neonates < 2000 grams can be obtained from Lexi-Comp, Inc. Online or from Bradley JS, 2016 Nelson's Pediatric Antimicrobial Therapy, 22nd edition. American Academy of Pediatrics., Elk Grove Village, IL.

TABLE 70.4

Comparison of Recommended Durations of Antibiotic Therapy for Meningitis From the Infectious Disease Society of America (IDSA) and the National Institute for Clinical Excellence (NICE)

Organism	IDSA Recommendations	NICE Recommendations
Streptococcus pneumoniae	10-14 days	14 days
Neisseria meningitidis	7 days	7 days
Group B streptococcus	14-21 days	14 days
Haemophilus influenzae	7 days	10 days

The duration of antimicrobial therapy will vary according to causative pathogen. Children with gram-negative bacterial meningitis require a minimum of 3 weeks. Classically, infants with group B streptococcal meningitis require 14 to 21 days; *S. pneumoniae,* 10 to 14 days; *N. meningitidis,* 7 days; and *H. influenzae,* 7 to 10 days. However, in certain clinical circumstances, a shorter duration may be feasible. A meta-analysis on duration of therapy in pediatric meningitis evaluated the three most common pathogens and compared short-course (4–7 days) versus long-course (7–14 days) therapy. There was no significant difference in clinical success or long-term neurologic complications between groups.[30] Subsequently, a multicountry trial enrolled more than 1000 children with meningitis caused by *H. influenzae* type b, *S. pneumonia,* or *N. meningitidis* who were stable after 5 days of intravenous (IV) ceftriaxone therapy and randomized them to receive placebo or an additional 5 days of ceftriaxone.[31] Again, there were no significant differences in bacteriologic failures, clinical failures, or clinical sequelae in survivors. The authors concluded that ceftriaxone could be discontinued in children with bacterial meningitis who are clinically stable after 5 days of IV therapy. Of note, patients with persistent seizures, bacteremia, brain abscesses, other infections, or who were judged to be severely ill at the 5-day mark were excluded.

The initial antibiotic regimen for community-acquired meningitis depends on the bacterial antibiotic resistance patterns in the area. In regions with less than 1% of *S. pneumoniae* isolates resistant to third-generation cephalosporins, ceftriaxone (plus ampicillin in areas with *L. monocytogenes*) should be initiated. In areas with more than 1% cephalosporin-resistant *S. pneumoniae,* ceftriaxone plus vancomycin is the empiric therapy of choice at present. Among newborns, cefotaxime plus ampicillin remains the treatment of choice. It is the opinion of many clinicians that ampicillin or penicillin G plus gentamicin are the agents of choice for group B streptococcal meningitis in the young infant. Alterations to these regimens may be influenced by Gram stain, culture, and drug susceptibility results. Additional empiric agents could be added according to epidemiologic exposures, underlying conditions, and the presence of resistant organisms in the community or hospital. Once a specific pathogen has been identified and susceptibility (antibiogram) data are available, antimicrobial therapy could be "narrowed" to specifically target the offending

pathogen.

There are increasing numbers of newer antibiotics that may have a role in meningitis management. Carbapenems may offer a treatment option in antibiotic-resistant strains causing meningitis. Imipenem is not recommended for CNS infections due to its proconvulsive association, but meropenem is as effective as ceftriaxone or cefotaxime as empiric therapy for bacterial meningitis. It can be considered for use in nosocomial meningitis either as a single agent or in combination with vancomycin. Linezolid, from the antibiotic class oxazolidinones, readily enters the CSF and is active against gram-positive organisms. Although primarily a bacteriostatic agent, it has been used successfully for CNS infections caused by multidrug-resistant organisms. Daptomycin, fluoroquinolones, tigecycline, and newer cephalosporins such as ceftaroline and ceftobiprole cannot be recommended as empiric therapy at this time but may have a role in individual cases of meningitis based on the organism's antibiograms.

Optimum therapy for childhood TB meningitis is unclear. No randomized controlled trials have been conducted. In drug-susceptible mycobacteria, the World Health Organization recommends 2 months of isoniazid, rifampicin, pyrazinamide, and ethambutol, with a subsequent 10-month course of isoniazid and rifampin. However, treatment length is controversial, with various experts advocating for 6 to 9 months of initial therapy.

Supportive Care

In addition to provision of an effective antimicrobial regimen, correction of hyponatremia, hypoxemia, and hypotension should also be included in the treatment plan of CNS infections. Rapid placement of an external ventriculostomy is indicated in patients with radiographic or clinical evidence of obstructive hydrocephalus. The presence of any of these along with a delay in CSF sterilization is associated with poor outcomes and neurologic sequelae.

In patients who present in shock or dehydration, administration of IV fluids is critical for the maintenance of normal blood pressure and proper perfusion. There has been disagreement regarding IV fluid management in patients with meningitis. There are potential risks from giving too much fluid (especially brain swelling) as well as too little fluid (especially shock). In a Cochrane review, the authors evaluated differing volumes of fluid given in the initial management of bacterial meningitis. Sadly, only three trials could be compared. All three trials were on pediatric patient groups. The meta-analysis found no significant difference between the maintenance-fluid and restricted-fluid groups in number of deaths, acute severe neurologic sequelae, or in mild to moderate sequelae.[32] However, when neurologic sequelae were further defined, there was a statistically significant difference in favor of the maintenance-fluid group for decrease in seizure activity at both 72 hours and 14 days, as well as less neurologic sequelae at 3 months. It must be noted that the reviewers mention the quality of evidence regarding fluid therapy in children with acute bacterial meningitis is marginal and there is a need for further research.

In patients with altered mental status, airway protection and assisted ventilation may be required. Patients who present in septic shock may require inotropes or vasopressors. Anticonvulsant therapy is indicated in patients with seizures. Consultation with infectious disease and pharmacy colleagues is often invaluable.

Adjunctive Therapy

The search for therapeutic adjuncts designed to improve therapy in meningitis is ongoing but often hampered by the difficulty in conducting randomized clinical trials due to the acuity of the disease, the narrow time frame in which adjuncts can influence outcome, and the increasingly small number of cases in this postvaccine era. Immunomodulation, hypothermia, free radical scavengers, C5 monoclonal antibodies, neutrophil proapoptosis agents, and toll-like receptor antagonists have all shown benefit in experimental models of meningitis.

Two agents, glycerol and dexamethasone, have been evaluated in pediatrics as possible adjuvant therapy in meningitis. The addition of adjunctive corticosteroids prior to antibiotic treatment in bacterial meningitis was endorsed by the Infectious Diseases Society of America (IDSA) guidelines in 2004. However, use of corticosteroids, such as dexamethasone, in meningitis has not been universally adopted among clinicians.

Oral glycerol has been shown to reduce neurologic sequelae in children with bacterial meningitis.[33] Its mechanism of action is unknown but possibly occurs through a reduction in serum viscosity, allowing for vasoconstriction with maintenance of cerebral blood flow and a subsequent reduction in cerebral blood volume.[34] Some clinicians believe glycerol may be more beneficial than corticosteroids as an adjuvant in decreasing neurologic sequelae.[35] Although promising, further investigations are required before empiric therapy with this agent can be recommended.

Corticosteroids are well studied in meningitis, although their exact beneficial mechanism of action remains obscure. In early studies in children with Hib meningitis, dexamethasone-treated children had a lower incidence of moderate-to-severe hearing deficits when compared to placebo.[36] However, one of the study's antimicrobial agents, cefuroxime, was later shown to be associated with increased neurologic sequelae. In adults with pneumococcal meningitis, the early administration of dexamethasone, 15 to 20 minutes before or with the first dose of antibiotic, was associated with a reduction in mortality and unfavorable outcomes.[37,38] In pediatric studies, dexamethasone did not demonstrate the same improvement in mortality noted in adults, but it was associated with an improvement in moderate-or-severe hearing loss.[39,40] There is no evidence that corticosteroid use is beneficial in viral or neonatal bacterial meningitis.[41]

A Cochrane database review examined the effect of adjuvant corticosteroid therapy on meningitis in both adults and children.[42] This meta-analysis included studies from 1966 through 2013. It reviewed 25 studies and demonstrated no reduction in mortality in either adult or pediatric-aged patients who received corticosteroids at some point in their meningitis management. However, subgroup analyses for causative organisms showed corticosteroids reduced mortality in *S. pneumoniae* meningitis but not in meningitis caused by *H. influenzae* or *N. meningitidis*. Additionally, corticosteroid recipients showed a significant reduction in hearing loss and neurologic sequelae. Interestingly, the benefit of corticosteroids was noted only in countries with higher socioeconomic classes. The Cochrane study ultimately recommended a 4-day regimen of dexamethasone, but it also remarked that the strength of evidence is not optimal.

Adjunctive steroid therapy reduces vasculitis associated with TB meningitis. In

addition, patients with TB meningitis treated with steroids have improved survival compared to nonrecipients. However, the severity of neurologic disability observed with TB meningitis is not altered.[43]

In summary, studies of adjuvant corticosteroid therapy in children have not unequivocally demonstrated beneficial effects. Study design flaws and the fact that most studies were done in the era of Hib disease limits the applicability of these results to today's practice. Meta-analysis and retrospective studies have demonstrated beneficial effects in Hib and pneumococcal meningitis. However, these were conducted at a time when drug-resistant *S. pneumoniae* (DRSP) was not a serious problem. The data could support a beneficial effect in Hib meningitis, but because this organism is an uncommon pathogen at this time, empiric therapy would not be warranted in most cases. In the era of DRSP, where an isolate may be resistant to the third-generation cephalosporin, it has been suggested that dexamethasone may impair the diffusion of vancomycin through the BBB, thus delaying CSF sterilization. Thus, caution is merited. Some clinicians recommend the addition of rifampin under these circumstances. Lastly, because maximal beneficial effect would be gained by administering dexamethasone prior to antibiotic therapy, children previously treated with antibiotics should not receive dexamethasone.

Prevention

Individuals with significant, prolonged, or close exposures (ie, household members and caregivers, daycare center playmates) to children with *N. meningitidis* meningitis should receive antimicrobial prophylaxis with ceftriaxone, ciprofloxacin, or rifampin.[44] However, ciprofloxacin resistance has been reported in the United States.[45] Thus antibiogram data are important in making antibiotic prophylaxis decisions.

Routine childhood vaccinations against Hib, *S. pneumoniae,* and *N. meningitidis* type A, C, W-135, and Y have significantly decreased the incidence of bacterial meningitis. Clinicians should recommend their use without hesitation. However, *N. meningitidis* type B continues to account for a majority of invasive meningococcal disease. In 2013, a vaccine against *N. meningitidis* type B was approved for use in Europe. Its effect on meningitis epidemiology is yet to be determined.

Outcomes

With aggressive support and appropriate antimicrobial therapy, the mortality rate of bacterial meningitis remains low. Unfortunately, neurologic sequelae still occur. When compared to other pathogens, pneumococcal, TB, and gram-negative bacillary meningitis are most commonly associated with neurologic sequelae. Seizures, hearing loss, hydrocephalus, and learning disabilities are the most common sequelae reported.

It is difficult to predict individual outcomes for a patient with meningitis admitted to the PICU. No single factor is entirely predictive. Among bacteria, *S. pneumoniae* is associated with the highest mortality. Interestingly, antimicrobial resistance in pneumococcal meningitis was not associated with death, ICU admission, need for mechanical ventilation, focal neurologic deficits, seizures, secondary fevers, or increased duration of hospital stay.[46] In a retrospective study of 15 PICUs in the

United States, patients with both bacterial and nonbacterial meningitis had an unadjusted mortality rate of 7%. Nonsurvivors had a significantly higher Pediatric Risk of Mortality III score. Mortality was threefold higher in patients with bacterial-confirmed meningitis. The presence of coma upon initial presentation to the PICU increased mortality 10-fold.[47] In another study evaluating only pneumococcal meningitis, the presence of shock, hyponatremia, or coma upon admission to the ICU was associated with a higher use of invasive medical devices and higher mortality.[48] A third pediatric study of all causes of meningitis showed factors associated with increased mortality included low Glasgow Coma Score, respiratory distress at presentation, seizures at any point during admission, and, in third world countries, malnutrition.[49] Among laboratory findings, the presence of low leukocyte blood cell and platelet counts was associated with increased mortality.[50,51]

The hippocampal formation is a region of the brain frequently affected in bacterial meningitis, a region of the brain known to be important in learning and memory.[52] A significant portion of meningitis survivors demonstrate neuropsychologic deficits and cognitive issues later in life. An educational outcomes evaluation showed that children recovering from CNS infections significantly underperformed on neuropsychologic evaluations in comparison to healthy controls.[53] Teachers noted children who recovered from CNS infections performed worse on educational assessments and had more problems with schoolwork. This group of children performed below average in both areas of executive function and attention. Analysis revealed that aspects of neuropsychologic function, such as memory function, and teacher-rated academic performance were most reduced in children with a history of meningoencephalitis.

Subdural Empyema

Subdural empyemas (SDEs) are serious central nervous system infections defined as purulent fluid collections outside the brain parenchyma but contained under the dura. They are usually encapsulated and often loculated. Historically, otorhinolaryngeal infections were an important predisposing factor to SDEs in older children. In a retrospective study over 24 years, the medical records of children with extraaxial CNS infection at a single children's hospital were analyzed. Over this time course, 70 children developed SDEs. Sinusitis was the most common etiology, followed by bacterial meningitis.[54] In this study, all patients were older than 7 years of age at diagnosis. However, another study that included infants demonstrated only 10% of SDE were related to otorhinolaryngeal infection.[55] This relatively low percentage is presumed to be from increased antibiotic use in this group of patients. In this study, meningitis, head trauma, or neurosurgery was identified as more common predisposing conditions for SDE. A third study, from 2001 through 2011, showed neurosurgical procedures were the most commonly identified source of infection.[56]

The pathophysiology of extraaxial CNS infections is well understood. Multiple predisposing etiologies are responsible, including extension of infection from regional sinuses, otitis, mastoiditis, and hematologic spread of pathogens from distant sites. In young infants, SDE is usually a complication of purulent meningitis wherein the infection extends through the arachnoid and into the subdural space.[57] Reactive subdural effusions can also occur following meningitis in infants. Though

often a source of fever, these fluid collections are typically sterile.

Certain presenting characteristics were specific to the various etiologic subgroups. Potts puffy tumors are found frequently among patients with prior sinusitis. In the pediatric population, extraaxial CNS infections are most common in two distinct age groups, corresponding to known etiologies. SDEs following meningitis are more common in infants, whereas sinus-related infections are most common in those older than 6 years of age.[58]

Fever, headaches, eye pain, and altered level of consciousness are common presenting features in SDE. Not unexpectedly, many of these symptoms are common to those suffering from sinusitis. An altered level of consciousness and focal neurologic deficits are frequently observed. Seizures and cerebral edema from cortical vein thrombosis are common complications among patients presenting with subdural empyemas.[59] Prolonged fever (90%), seizures (70%), and focal neurologic signs (60%) are the most common clinical signs noted in the pediatric population.[55] The sequelae of SDE may be more severe in young infants than in any other age group.[60]

Historically, in children, SDE was often secondary to *H. influenzae* type b or *S. pneumoniae* meningitis. SDE also occurs with *Salmonella, N. meningitides, E. coli,* and TB. Streptococcus species and *S. aureus* were the most common pathogens identified.[54,56] The most common pathogen in infants younger than 4 months of age is group B streptococcus.[55]

The diagnosis is often made with radiologic assistance and evaluation of the subdural fluid collection. It is often difficult to distinguish an SDE from a sterile reactive subdural effusion (RSE).[61] The differentiation of SDE from sterile RSE may not be possible if contrast enhancement of the inner membrane is not seen on CT. MR imaging is superior to CT in the demonstration of both the extraaxial fluid and the enhancement of the inner membrane with a paramagnetic contrast medium. Still, no MR imaging characteristics are specific for SDE compared to a sterile RSE. Analysis of the subdural fluid is often required to establish the diagnosis of SDE. Serial cranial ultrasounds may be the modality of choice for the evaluation of response to medical management.[62]

The goal of treatment is evacuation of pus and eradication of the source of infection. Management choice should be related to the clinical condition. Medical treatment may be adequate if the empyema is small. A surgical approach is suggested in those patients who are not responding well to medical treatment or in those who have massive subdural pus accumulation. Craniotomy is the preferred procedure in most cases (Fig. 70.1). In young infants, a subdural tap through the anterior fontanel or bur hole is the preferred mode of intracranial pus evacuation because of ease of access. Many patients require repeated surgical procedures due to empyema recurrence.

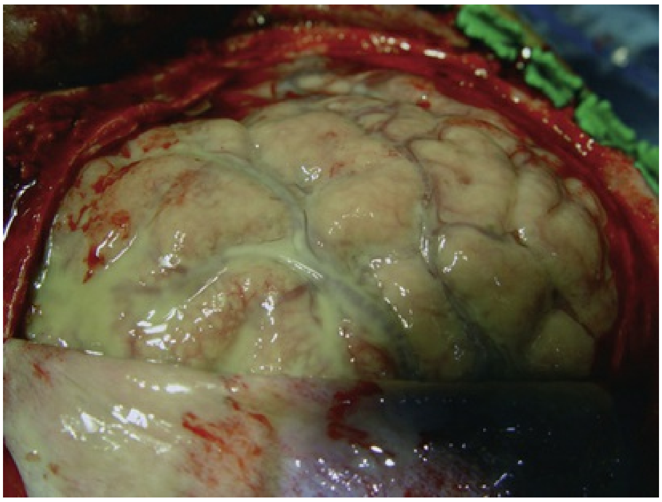

FIG. 70.1 Operative photograph of a patient with cranial subdural empyema. (Courtesy Alan R. Turtz, MD, Cooper University Hospital, Camden, NJ.)

The keys to an optimal outcome are early, accurate diagnosis, timely intervention, and appropriate antibiotic therapy. The reported mortality rates of SDE are approximately 10% following meningitis and up to 20% following untreated sinus infections.[63]

Germiller and colleagues reported a 4% mortality rate in a pediatric series of intracranial suppurative infections.[64] Survivors often had significant long-term morbidity with persistent seizures, hemiparesis, or residual neurologic deficits. Age, initial level of consciousness, timing and aggressiveness of treatment, and the rapidity of disease progression all influence outcome.

SDEs are rare and difficult to diagnose because initial symptoms may be vague. Patients with sinus infections and progressive headaches or any neurologic deficits should be evaluated with CT or MRI imaging to rule out intracranial spread. Because SDEs have serious morbidity and mortality if not recognized and treated promptly, the ICU physician must have a low threshold for requesting emergency neurosurgical intervention.

Brain Abscesses

The brain parenchyma is remarkably resistant to microbial infections. Despite the relative frequency of occult bacteremia in the pediatric-age patient, cerebral abscess formation is a rare occurrence. A brain abscess is an intraparenchymal infection that begins as a localized area of cerebritis and evolves through various stages until finally organizing into a collection of encapsulated purulent material. Among intracranial masses, the incidence of brain abscess is ~8% in developing countries and ~1% to 2% in Europe and North America.[65] Incidence of brain abscesses in children is 4 cases per million, with a peak age of presentation between 4 and 7 years of age.[66] Certain medical conditions, especially those that impair the immune response, predispose patients for an increased incidence of brain abscess formation. These include prolonged steroid use, diabetes mellitus, alcoholism, and primary immunodeficiencies.[67] At a single children's hospital over a 19-year period, congenital heart disease and sinus/otic infections were the most common predisposing factors to development of cerebral abscesses.[68]

Brain abscesses are often classified according to their likely point of entry. The most common origin of CNS abscesses in children is direct or indirect extension from the middle ear, paranasal sinus, or dental abscesses.[69] Brain abscesses are sequelae in 65% to 8% of untreated sinusitis cases and up to 10% of mastoiditis cases.[66] Abscesses in the temporal lobe or cerebellum are typically linked to ear or mastoid air cell points of entry and tend to be solitary. Frontal and parietal lobe abscesses are often due to sinus or dental infections (Fig. 70.2).

FIG. 70.2 Head CT demonstrating a large brain abscess in the parietal lobe associated with sinusitis. Cultures grew *Streptococcus* spp.

Abscesses of hematogenous origin are often noted in specific CNS parenchymal areas, especially in the middle cerebral artery distributions including the parietal and occipital regions (Fig. 70.3). The etiology of these multiple foci is often from distant sources in children with cardiac or pulmonary right-to-left shunts. Not surprisingly, cyanotic heart disease increases the risk of brain abscess formation.[66,70] In patients diagnosed with a brain abscess, a third will have an underlying heart defect.[71] Of these, tetralogy of Fallot, transposition of the great vessels, atrial septal defects, ventricular septal defects, and the Eisenmenger complex are reported to predispose children to brain abscesses. This increased predisposition may be due to the presence of areas of brain ischemia caused by decreased arterial oxygen saturation and increased hemoglobin, which may act as a focus for infection to develop. Right-to-left shunting may also predispose to brain abscess, as the removal of organisms from the systemic circulation by the lungs is bypassed. Hematogenous spread can also occur by way of the veins that drain into the cavernous sinus, resulting in frontal lobe abscesses that correlate with infections of the facial tissues or ethmoid sinuses.

FIG. 70.3 MRI demonstrating multiple brain abscesses in a patient with cyanotic heart disease and single ventricle physiology. (Image courtesy of John Christenson, Indiana University.)

Extensions from cranial osteomyelitis, scalp infections, endocarditis, and meningitis are other known causes of CNS abscess formation. Several studies examined the etiology of brain abscesses in noncardiac patients. Incidence is reported as endocarditis in 10% of patients, bacteremia in 8%, immune deficiency in 12%, pulmonary anomalies in 5%, and skin folliculitis in 3%.[72,73] Infants and toddlers are more susceptible than other age groups to brain abscesses arising as complications of bacterial meningitis or bacteremia.[74] Historically, penetrating head trauma and neurosurgery represent a small proportion of the predisposing causes of CNS abscess, but the proportion is increasing, possibly as other predisposing factors such as middle ear infection become less important. In roughly one quarter of brain abscess cases, no identifiable route or predisposing factors are identified.[69]

Abscess formation results from the seeding of the parenchyma as the result of hematogenous spread from remote sources, direct invasion from contiguous infection of non-neural tissues, or from implantation of pathogens following penetrating wounds or surgery. Histologically, brain abscesses typically begin as areas of cerebritis with foci of acute inflammation. Vascular dilation, microthrombus formation, and rupture of small vessels are all noted. After 4 to 9 days, the center of the lesion undergoes liquefaction necrosis. By 10 to 14 days, a well-vascularized collagenous capsule with peripheral gliosis or fibrosis is typically present (Fig. 70.4).

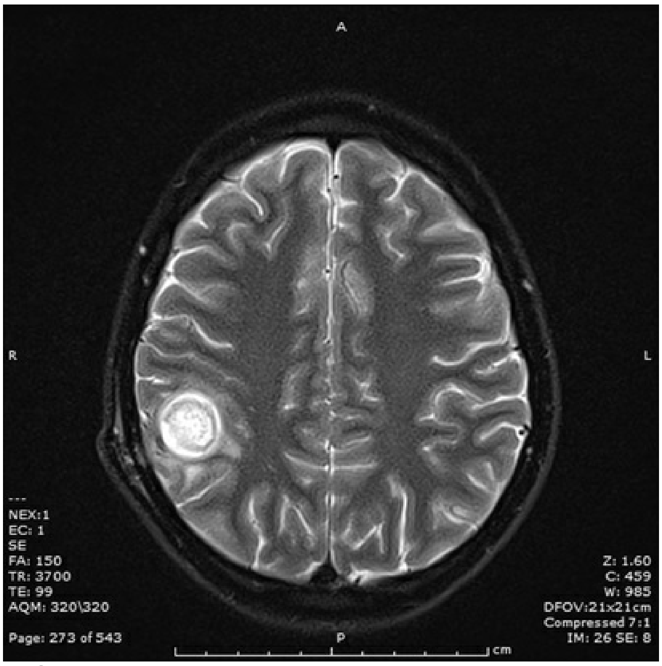

FIG. 70.4 Solitary brain abscess on MRI demonstrating evidence of liquefaction necrosis and a well-vascularized collagenous capsule. (Image courtesy of John Christenson, Indiana University.)

The clinical presentation varies, depending on the size, multiplicity, and location of the lesion. Most patients are symptomatic within a week of the onset of abscess formation. Symptoms in adults are nonspecific and include headache (70%), fever (60%), vomiting (50%), focal neurologic deficits (45%), and seizures (40%).[69,75] Clinical symptoms occur even less commonly in pediatric cases. The triad of fever, headache, and focal deficits occurs in less than 30%, whereas meningeal signs occur in less than 25%.[76] Among clinical signs, over half of the cases will have papilledema. The sudden worsening of a preexisting headache can indicate rupture of the brain abscess into the ventricular space or impending herniation from the lesion's mass effect. Significant alteration in mental status is an ominous clinical finding. Children with abscesses located within their brain stem typically present with fever, headaches, hemiparesis, and often have cranial nerve palsies of III, VI, and VII.

The most important microbiologic investigation in the management of patients with brain abscess is culture of the abscess fluid. The widespread acceptance of CT-guided stereotactic aspiration of brain abscesses, a minimally invasive procedure with low morbidity and mortality, is often indicated. This procedure allows both rapid and effective surgical drainage of the brain abscess and obtains material for culture. Lumbar puncture to obtain CSF may be contraindicated in a patient with a brain abscess, as raised ICP may lead to brain stem herniation in these patients. Additionally, CSF culture does not contribute significantly to the identification of the organism. Blood cultures can be helpful in a small percentage of patients, especially in those in whom the abscess is thought to be the result of hematogenous spread.

The microorganisms cultured from the brain abscess are variable and often depend on the original source. *S. aureus*, *Streptococcus* spp., and gram-negative anaerobic bacilli tend to predominate. *Citrobacter* and *E. sakazakii* are frequently associated with brain abscesses in neonates. In children with impaired host defenses, fungi and uncommon pathogens such as *Toxoplasma*, *Nocardia*, and *Mycobacterium*

can be identified. Mixed aerobic and anaerobic flora are isolated in up to a third of patients, especially children with chronic otitis and sinusitis.[77] A quarter of abscess samples may demonstrate no bacterial growth.

Because the clinical presentation of brain abscess is often nonspecific, the diagnosis is often made by CT. Without imaging, it may be difficult to differentiate between brain abscess and other intracerebral pathologic processes. The advent of CT has altered the prognosis of brain abscess by improving diagnosis. MRI is also a useful tool in diagnosis but has not yet been shown to be superior to CT in establishing diagnosis. MRI may have a diagnostic advantage over CT by better differentiation of edema from liquefaction necrosis and greater sensitivity for early detection of satellite lesions.[78] Both CT and MRI are able to locate the position of the abscess accurately, thus enabling a focused surgical intervention. Serial CT scanning may provide additional information about response to treatment.

There have been no randomized, controlled trials comparing the various treatments for brain abscesses. The neurologic status of the patient, the location of the abscess, the number/size of the abscesses, and the stage of abscess formation should influence medical management. Stereotactic CT-guided drainage of the abscess, followed by antibiotic therapy, is the treatment of choice in most patients. Typically, abscesses >2.5 cm require surgical drainage.[79] Even in the critically ill PICU patient, a stereotactic procedure is minimally invasive and the risk-benefit profile will often support its use. Aspiration of the abscess allows both removal of infected nidus and likely identification of the causative organism. Endoscopic drainage may be useful in lesions located in a periventricular distribution.

Craniotomy and excision are usually reserved for abscesses that enlarge after 2 weeks of antibiotic therapy or that fail to shrink after 3 to 4 weeks of antibiotics.[80] Craniotomy is also recommended for multiloculated abscesses and larger lesions with significant mass effect. Craniotomy and direct surgical drainage are required in some cases of fungal or helminthic infections or after failed stereotactic drainage. Also, brain abscesses secondary to traumatic brain injury should be considered strongly for surgical excision because of the possibility of retained foreign bodies or bone fragments. Lesions located in the cerebellum may have a lower mortality, incidence of developing obstructive hydrocephalus, and shorter hospital stays if primary excision is chosen over stereotactic aspiration.[81]

There are few indications for the nonoperative management of brain abscesses. These include patients with surgically inaccessible lesions, early cerebritis, multiple small abscesses, or medical comorbidities that would classify the patient as high risk. In specific cases where there is a small lesion and the infecting organism is known, medical treatment alone may be considered appropriate.

A combination of a third generation cephalosporin and metronidazole is a reasonable combination for initial antibiotic therapy in brain abscesses. Vancomycin can be added if *S. aureus* is identified or suspected as the causative organism. Vancomycin is also a reasonable choice if the abscess is believed to have occurred as a consequence of a neurosurgical procedure. There are no prospective studies in children to guide antibiotic therapy. Duration of treatment is typically based on clinical response. Duration can be as short as 1 to 2 weeks of IV antibiotic therapy followed by 2 to 4 weeks of an oral antibiotic after surgical drainage. Some clinicians recommend duration of IV therapy as long as 4 to 6 weeks.[78] If antibiotics alone are utilized, duration of IV therapy is typically longer, with some clinicians

recommending up to 6 to 8 weeks.[79]

Mortality attributed to brain abscess was 60% prior to 1970. Since the advent of newer radiologic procedures such has high-resolution head CT or MRI, detection of brain abscesses is more efficient. With earlier detection, mortality has dropped and currently is about 10% to 15%.[75,76] Long-term neurologic morbidity attributed to the abscess and therapy ranges from 10% to 30% depending on both size and location of the lesion as well as response to therapy. The patient's neurologic status at presentation is a significant predictor of outcome with an increased mortality rate in those who present to the PICU with an altered mental status or rapid neurologic deterioration.[82] Brain abscesses resulting from a contiguous focus of infection and those developing after a traumatic injury tend to have a good prognosis. Those resulting from patients with immunologic or cardiac predisposing factor are more likely to have a poorer outcome.

Viral Meningoencephalitis

The incidence of bacterial meningitis has decreased significantly in the vaccine era. However, viral meningoencephalitis continues to be a common neurologic problem in the PICU. The initial signs and symptoms are often indistinguishable from bacterial meningitis, and a diagnosis of a viral, rather than bacterial, CNS infection does not correlate with decreased morbidity or mortality.

Whereas meningitis implies that the meninges are primarily involved, encephalitis indicates brain parenchymal involvement. The presence or absence of normal brain function is important in distinguishing between meningitis and encephalitis. Patients with meningitis typically have fever, meningeal signs, CSF pleocytosis, and no associated neurologic dysfunction unless related to seizure activity or elevated ICP. Abnormal neurologic findings such as focal neurologic signs, cranial nerve involvement, motor deficits, sensory deficits, or speech difficulties suggest brain parenchymal involvement and encephalitis. Patients presenting with seizures may have meningitis or encephalitis. Making the distinction between meningitis and encephalitis is often difficult, and patients may present with both a parenchymal and meningeal process. Therefore, some authors prefer the term *meningoencephalitis* to recognize the inherent overlap between the two clinical entities.

Epidemiology

A survey of hospital discharge records from 1988 to 1997 showed approximately 19,000 hospitalizations per year (7.3 hospitalizations per 100,000 population), 230,000 hospital days, and 1400 deaths annually due to viral encephalitis in the United States.[83] Children under the age of 1 year had the highest risk for hospitalization due to encephalitis. Between 1989 and 1998, there were approximately 1100 deaths due to encephalitis in children under the age of 19 in the United States. The highest rate of death was in children less than 1 year of age (9.3 per 100,000 population).[83] Although the causative agent in encephalitis can be difficult to isolate, most cases are attributed to enteroviruses, herpesviruses, and arboviruses. The enteroviruses and arboviruses in particular display seasonality in infection, being seen most frequently in the summer and autumn months. Herpesviruses, cytomegalovirus (CMV), varicella-zoster virus (VZV), and Epstein-Barr virus (EBV) often show a predilection

for the winter and spring. Herpes simplex, however, does not demonstrate any seasonality. With this epidemiology in mind, the evaluation of children with suspected viral meningoencephalitis is guided by many factors including age, geographic location, season of the year, vaccination status, chronic conditions or immunosuppression, history of tick or mosquito exposure, and travel history.

Pathophysiology/Pathogenesis of Viral Meningoencephalitis

Infection of the CNS by most neurotropic viruses begins with multiplication of the virus at the port of entry (mucosal surfaces of the skin, gastrointestinal tract, or respiratory tract). The viruses then travel to extraneural sites in the body. They then migrate to vascular tissue, further multiply, and, finally, infect the CNS. Viruses may reach the CNS by several mechanisms. Although most directly invade across cerebral capillary endothelial cells that comprise the BBB, they may also (1) directly infect cerebral microvascular endothelial cells before infection of adjacent glia and neurons, (2) be carried between cerebral endothelial cells in infected leukocytes after BBB disruption, (3) initially infect glia without evidence of endothelial cell infection, (4) enter the choroid plexus epithelium, or (5) spread along olfactory nerve or peripheral nerve pathways.[84] Once a virus has invaded the CNS, it attaches within susceptible cells and induces the cellular changes and inflammatory responses that manifest as meningitis or encephalitis.

Clinical Evaluation

Bacterial and other causes of meningoencephalitis as well as other causes of encephalopathy such as trauma, hepatic failure, electrolyte abnormalities, and toxic ingestions must be ruled out before viral encephalitis is diagnosed. A careful history will yield important information such as immunization status, recent viral or other infections, history of immune diseases, travel history, tick or mosquito exposure, and the history of maternal herpes infection in the case of neonates. Physical exam should focus on evaluation of the mucous membranes and skin as well as a complete neurologic examination including the funduscopic examination. A high level of suspicion and vigilance, with serial neurologic examinations, is essential because viral injury may result in the development of cerebral edema and even brain stem herniation. As in meningitis, antibiotics or antiviral medications should not be withheld while the laboratory and imaging workup of encephalitis is pursued.

Laboratory Manifestations

Lumbar puncture with an opening pressure is essential in the evaluation of the patient with suspected meningoencephalitis. Initial evaluation of CSF includes cell count, protein, glucose, culture, herpes simplex virus (HSV) PCR, enteroviral PCR, and oligoclonal bands.[85] CSF findings in viral encephalitis include pleocytosis with white blood cell counts in the 100 to 1000 cells/uL range. Polymorphonuclear cells are often predominant in early infection and even up to 48 hours of infection; lymphocytes typically become more predominant later in the time course.[86] There is usually at least mild elevation in CSF protein, and there may be mildly decreased

glucose; however, glucose is often normal. Elevated red blood cells are often seen with herpesvirus. In addition to CSF, blood should be obtained for complete blood count and culture, erythrocyte sedimentation rate or C-reactive protein, and electrolytes. If suggested by the history, additional studies for viral studies should be obtained. These often include CSF and serum arboviral titers (virus-specific IgM) and serum, urine, or nasal specimens for viruses such as HSV, varicella, EBV, CMV, adenovirus, influenza, and parainfluenza.

As a more rapid alternative to tissue culture, PCR techniques allow for relatively sensitive and specific diagnosis of enteroviruses and herpesviruses in the clinical setting. For enteroviruses, PCR is directed at genomic RNA in the highly conserved regions of the 5′ noncoding region. PCR allows for accurate diagnosis of enteroviruses in a few hours, and sensitivity has been shown to be approximately 98%.[87] Specific virologic diagnosis of enteroviruses requires recovery of virus from CSF or tissue culture, with a sensitivity of 65% to 75%.[88] For HSV, CSF PCR is the test of choice, with approximately 98% sensitivity and 94% specificity.[89,90] PCR for VZV DNA has been found to be 95% specific but only 30% sensitive. Therefore, it is recommended that in cases of suspected VZV encephalitis the CSF be tested for intrathecal synthesis of VZV-specific antibody (IgM and CSF-to-serum IgG ratio).[91,92] PCR testing is also available for EBV and CMV from the CSF. For HHV-6 infection, which may present as severe encephalitis in immunocompromised patients, PCR has been shown to be somewhat sensitive; however, it may unreliably detect the virus, and viral isolation may be required.[93,94]

Arboviruses in the CSF and serum are detected by IgG and IgM antibody testing. According to criteria of the Centers for Disease Control and Prevention (CDC), confirmed cases of arboviral disease must demonstrate (1) a fourfold or greater change in virus-specific antibody titer; (2) isolation of virus from or demonstration of specific viral antigen or genomic sequences in tissue, blood, or CSF; (3) virus-specific IgM in CSF by antibody-capture enzyme immunoassay (EIA); or (4) virus-specific antibodies demonstrated in serum by antibody-capture EIA and confirmed by IgG antibodies in either the same or a later specimen.[95] Many states have epidemiologic programs to provide surveillance of arboviral infections, and consultation with local and state health departments will help guide serologic testing.

In some rare cases, brain biopsy is required for definitive diagnosis and remains the gold standard to diagnose viral infections of the CNS.

Neuroimaging

The initial noncontrast head CT may be normal in patients with meningoencephalitis. Although most patients will undergo a CT scan in the early period of illness, MRI is most sensitive for detecting inflammation, edema, and hemorrhage in viral encephalitis. If there is concern for spinal cord involvement (transverse myelitis, enterovirus), then the MRI should also include the spine.[95] Depending on disease severity, patients with viral encephalitis may show focal or diffuse cerebral edema and even uncal or transtentorial herniation on either CT or MRI.

Specific infections often show characteristic MRI findings that may be helpful in formulating a diagnosis. The MRI appearance of viral encephalitis is generally that of diffuse scattered or confluent areas of T2-weighted hyperintensity. There is a

variable degree of mass effect and edema. Inflammation often involves meninges, and gadolinium enhancement is diffuse. The classic finding in HSV and HHV-6 encephalitis is hemorrhagic inflammation, often bilateral, of the temporal lobe, which manifests as T2-weighted hyperintensity on MRI and usually spares the deep nuclear structures (Fig. 70.5).[96,97] Neonates with HSV encephalitis may demonstrate less defined areas of inflammation on MRI and may have a loss of gray-white matter distinction only.[95] Among other herpesviruses, VZV encephalitis may demonstrate multifocal ischemia and infarction as well as demyelinating lesions in the white matter and at gray-white junctions. CMV often shows characteristic enhancement in the ependyma around the lateral ventricles.[97] Togaviruses, including West Nile virus, St. Louis encephalitis virus, Japanese encephalitis virus, and Eastern and Western equine encephalitis viruses, show involvement in the subcortical white matter, thalami, and substantia nigra.[97] In particular, Eastern equine encephalitis has been shown to produce focal lesions in the basal ganglia, thalami, and brain stem.[98] MRI findings in enterovirus encephalitis are less clearly defined and may be highly variable. However, patients with enterovirus 71 infection have demonstrated increased T2 and fluid-attenuated inversion recovery (FLAIR) signal intensity in the midbrain, pons, medulla, and even the spinal cord.[99]

FIG. 70.5 Classic temporal lobe enhancement noted on a head T2-weighted MRI in a patient with herpes simplex virus encephalitis. (Image courtesy of Karen Bloch, Vanderbilt Medical Center.)

Clinical Presentation and Course

The clinical course of viral meningoencephalitis is highly variable, ranging from mild disease to death. Children with viral meningoencephalitis or encephalitis usually present with a prodrome of fever, headache, irritability, malaise, decreased oral intake, nausea, and possibly neck pain or nuchal rigidity. These signs and

symptoms are essentially identical to the presentation of viral meningitis. However, a child with encephalitis also shows a decline in the level of consciousness and may demonstrate confusion, ataxia, seizures, aphasia, visual changes, and focal motor deficits or sensory deficits corresponding to the affected areas of the brain. In general, the most common focal neurologic deficits seen in encephalitis are hemiparesis, aphasia, ataxia, cranial nerve palsies, seizures, and myoclonus. Patients may also demonstrate autonomic dysregulation or hypothalamic dysfunction resulting in diabetes insipidus or syndrome of inappropriate antidiuretic hormone (SIADH). Seizures are possible, especially in infants and children with herpes encephalitis. At the most extreme end of the encephalitis spectrum, focal or diffuse cerebral edema and even brain stem herniation may occur.

HSV, from either a new infection or a latent reinfection, remains the most common cause of fatal sporadic encephalitis in humans, despite specific antiviral therapy.[100] HSV encephalitis is particularly severe in children with immunocompromise due to chemotherapeutic regimens, genetic immune defects, or human immunodeficiency virus infection. Children and adolescents with HSV encephalitis present with nonspecific neurologic signs and often have seizures. Support for the diagnosis of HSV encephalitis may be bolstered by findings of temporal lobe involvement on MRI as well as spike and slow-wave activity on EEG.[101] Adults and children typically present with HSV-1 infection. In neonates, the majority of encephalitis cases are caused by HSV-2 due to perinatal transmission and shedding of virus in the maternal genital tract. Neonates presenting with encephalitis due to HSV often do not demonstrate fever. Skin lesion findings are variable. The most common presenting signs for neonates with HSV CNS disease are seizures and lethargy.[102] Infants with HSV infection may also have disseminated disease, which increases the risk of morbidity and mortality significantly. However, as the majority of infants with HSV encephalitis are <21 days of age, testing for HSV without specific symptoms or radiologic findings and broad use of empiric acyclovir in older infants and children may be unnecessary.[103,104]

Enteroviral encephalitis may be highly variable in its presentation. The majority of cases are self-limited, but a large proportion of patients experience at least short-term morbidity. Although HSV has predilection for the temporal lobes in many cases, the enteroviral infections are more global in nature in general. Patients with enteroviral encephalitis often present with fever, headache, nausea, vomiting, and nuchal rigidity. They may also demonstrate confusion or delirium as well as have seizures or focal neurologic signs.[105]

Enterovirus 71, the cause of hand-foot-mouth disease/herpangina, usually causes flulike symptoms and a characteristic rash on hands, feet, and buttocks and oral ulcers. It can also cause flaccid paralysis, inflammation and necrosis of the tissues of the brain stem, and death in about 16% of cases.[106] In addition, myocarditis and heart failure have also been reported with enterovirus 71 infections. Severe enterovirus 71 outbreaks were originally described in Asia. High fever and lethargy predict severe disease, and myoclonus often indicates early brain stem involvement. PCR of throat swabs and vesicle fluid, if available, is among the diagnostic tests of choice. Features of inflammation, particularly in the anterior horns of the spinal cord, the dorsal pons, and the medulla can be seen on MRI. Although there is no established antiviral treatment, intravenous immunoglobulin (IVIG) seems to be beneficial in severe disease, perhaps through nonspecific antiinflammatory mechanisms.[107] This virus

may represent an important worldwide emerging pathogen.[108] Unfortunately, the neurodevelopmental follow-up of children with severe enterovirus 71 brain stem encephalitis reveals significant long-term cognitive and motor deficits.[109,110]

Neuroinvasive arboviral infections include the California serogroup viruses, Eastern and Western equine encephalitis viruses, Powassan virus, St. Louis encephalitis virus, and West Nile virus. Their incidence increases when mosquito vectors are most active, usually in the summer months, and incidence varies significantly based on geographic region. This group causes encephalitis as well as myelitis. In fact, West Nile virus infection has been misdiagnosed as Guillain-Barré syndrome due to flaccid paralysis. Arboviral encephalitis is characterized by fever, headache, and altered mental status ranging from confusion to coma, with or without additional signs of brain dysfunction. Arboviral myelitis causes acute bulbar or limb paresis or a flaccid paralysis.[111] A review of data from ArboNET, the national arboviral surveillance system in the United States, published in 2014 found 1217 cases and 22 deaths due to pediatric neuroinvasive arboviral infections from 2003 through 2012. La Crosse virus (665 cases, 55%) and West Nile virus (505 cases, 41%) were the most common viruses identified. However, Eastern equine encephalitis was the most deadly, causing 10 deaths out of 30 cases identified.[112] West Nile virus occurred throughout the United States, whereas La Crosse virus was most common in the Appalachian and Midwestern regions (Tennessee, West Virginia, North Carolina, and Ohio). Eastern equine encephalitis virus is most common along the Atlantic and Gulf coasts of the United States. Many arboviruses show increased incidence in boys, and it is unclear whether this is related to increased outdoor activity in boys or a true sex-based predilection.

Other zoonoses can cause encephalitis. Exposure to tick populations may suggest infection with Colorado tick fever in the western United States or nonviral etiologies such as Lyme disease or Rocky Mountain spotted fever. Nipah virus encephalitis has been seen in Malaysia, Singapore, and Bangladesh and may be associated with bat or pig exposures.[113-115] Lymphocytic choriomeningitis virus is caused by a rodent-borne arenavirus and is transmitted via mice, rat, and hamster secretions. Rabies, while rare in the United States, should be suspected in patients with prodromal symptoms of encephalitis followed by hydrophobia and pharyngeal spasms as well as exposure to bats or other reservoirs. The incubation period is typically 20 to 60 days but can be in the 5-day to 6-month range.[116] In the developing world, canine rabies transmission to humans remains a significant public health problem, with an estimated (but probably severely underestimated) 55,000 deaths annually in Africa and Asia.[117]

Influenza virus infection has been associated with a number of neurologic complications such as seizures and mild encephalopathy.[118] The neuroimaging of many of these patients demonstrates a distinct pattern of bilateral, multifocal lesions of the thalami that have been described as acute necrotizing encephalopathy.[119,120] In addition, many patients with influenza-associated encephalitis and necrotizing encephalitis progress to multisystem organ failure. In a survey of more than 140 cases in Japan during the 1998–1999 influenza A (H3N2) outbreak, 31.8% of patients with influenza-associated encephalitis or encephalopathy died and another 27.7% experienced either short- or long-term disability.[121] Brain CT revealed abnormalities in 66% of patients, with the most frequent findings being cerebral edema and hypodensities in the thalamus, brain stem, and brain parenchyma. Approximately 10% of the patients in the 1998–1999 case series showed the characteristic findings of

acute necrotizing encephalopathy. Only a small number of these patients have had influenza RNA isolated from CSF, and autopsies demonstrate a lack of direct viral invasion in the central nervous system. Many of the cases have been described in Japan and other parts of Asia, leading to some speculation that there may be a genetic susceptibility to developing influenza-associated encephalitis/encephalopathy, but cases are also described in Europe and North America.[122-124]

Treatment

With the exception of herpesviruses, therapy for patients with HSV encephalitis is largely supportive. Those with severe neurologic dysfunction or status epilepticus may require airway, respiratory, and circulatory support. Clinicians should maintain careful attention to fluid and electrolyte status due to the risk of diabetes insipidus, SIADH, and cerebral salt wasting. ICP monitoring has been used at some centers, and therapies to decrease intracranial pressure may be required.[125] Several small case series and case reports have discussed the use of decompressive craniotomy or craniectomy in the setting of severe encephalitis-induced intracranial hypertension in both adults and children.[126] However, to date there have been no large studies on the outcomes of children with severe viral encephalitis and intracranial hypertension managed with ICP monitoring or decompressive craniectomy. Seizures, both clinical and subclinical, should be treated and subsequently prevented as much as possible. Continuous EEG monitoring and barbiturate coma have been used in selected cases; however, the literature suggests that patients with refractory status epilepticus and viral encephalitis have extremely poor outcomes.[127]

Medical treatment of viral encephalitis is most effective in treatment of herpesvirus. In neonates with HSV encephalitis, antiviral therapy has significantly improved survival and decreased disease progression. The current recommended treatment for patients from infancy to age 12 years with HSV encephalitis is "high-dose" acyclovir (20 mg/kg IV every 8 hours) given for 21 days for both encephalitis and disseminated disease. Those over 12 years of age should receive acyclovir at 30 mg/kg per day in three divided doses for 21 days.[128] Acyclovir-resistant HSV infections, though rare, have been reported and treated with foscarnet.[129]

Infants born to mothers who contract primary varicella infection from 5 days prior to delivery until 2 days after delivery are at increased risk for severe varicella encephalitis. Exposed newborns may be candidates for VZV specific immunoglobulin prophylaxis (VariZIG) if the mother has severe skin involvement. There is a paucity of data, but the use of IV acyclovir at doses identical to treatment for HSV infection is recommended for neonates with clinical signs of varicella due to the risk of severe disease. Intravenous acyclovir therapy is also recommended for other pediatric patients with encephalitis as well as immunocompromised patients with any form of varicella disease. Children with varicella should not receive salicylates due to the increased risk for Reye syndrome, and those on chronic salicylate therapy for other conditions should have their salicylate suspended. Like HSV, acyclovir-resistant varicella has been treated with foscarnet.

Case reports of immunocompromised patients with human herpesvirus 6 (HHV-6) encephalitis suggest that this may be an emerging pathogen, particularly among transplant recipients.[130] Encephalitis may be caused by either a new infection or a

reactivation of latent HHV-6. Isolation of HHV-6 from the blood or detection of viral DNA in serum or plasma via PCR indicates active viral infection. Serology is considered unreliable, particularly in immunocompromised patients. Foscarnet, ganciclovir, and cidofovir have been shown to have efficacy against HHV-6, and the International Herpes Management Forum recommends foscarnet and ganciclovir, either alone or in combination, for treatment of HHV-6-related central nervous system illness.[131]

CMV has caused encephalitis in immunocompromised patients and is particularly fatal in HIV disease. Foscarnet-ganciclovir combination therapy has been used with limited success.

Influenza encephalitis remains a challenge because often the virus is not detected in the CSF or even in brain tissue specimens. The neuraminidase inhibitor oseltamivir as well as the ion channel blocker amantadine were both used in the largest prospective study of acute encephalitis/encephalopathy and influenza. It is unknown whether these agents change the outcome of this particularly clinically diverse and evolving entity.[132] Despite antiviral therapy, influenza encephalitis is frequently fatal.

Prognosis

The prognosis for patients with meningoencephalitis is extremely variable and depends on the causative agent and the degree of CNS injury. Some patients with relatively mild disease may experience only short-term sequelae of their infection. Although antiviral therapy has significantly improved mortality for HSV encephalitis in neonates, studies suggest that the long-term cognitive and neurodevelopmental consequences for survivors of HSV encephalitis and disseminated HSV disease include static encephalopathy, mental retardation, autism, cortical blindness, and epilepsy. Focal signs on neurologic exam, multiple seizures or status epilepticus on admission, leukopenia, and focal slow waves or continuous generalized delta waves on EEG are all associated with poor neurologic outcomes.[133] Serial neuroimaging studies and close neurologic follow-up may aid in counseling families regarding the prognosis for individual patients, but predicting neurologic functional outcomes in this group of patients remains a challenge for clinicians.

Central Nervous System Amebic Infections

Free-living amebas found in freshwater environments cause rare, often fatal forms of meningoencephalitis affecting both the brain and spinal cord. The three most common organisms are *Naegleria fowleri, Acanthamoeba* species, and *Balamuthia mandrillaris. Naegleria* causes primary amebic meningoencephalitis (PAM). *Acanthamoeba* and *Balamuthia* cause granulomatous amebic encephalitis (GAE).

PAM is a rare, often fatal disease most commonly caused by infection with *Naegleria fowleri,* a thermophilic, free-living ameba found in freshwater environments. *N. fowleri* is the causal agent of most PAM infections, but other species of *Naegleria* having pathogenic potential have been described (*N. australiensis, N. italica*). Currently, more than a dozen species of *Naegleria* are recognized based on small subunit ribosomal DNA.[134] The habitat for *N. fowleri* is natural or man-made

freshwater lakes or an inadequately chlorinated swimming pool where the amebas can feed on bacteria and proliferate. In the United States, *N. fowleri* is commonly found in warm freshwater environments in 15 southern tier states (Arizona, Arkansas, California, Florida, Georgia, Louisiana, Mississippi, Missouri, Nevada, New Mexico, North Carolina, Oklahoma, South Carolina, Texas, and Virginia).

In the United States, 111 PAM patients were diagnosed, reported, and verified by state health officials between 1962 and 2008. These infections occurred primarily in previously healthy young males exposed to warm recreational waters, especially lakes and ponds, during summer months. The annual number of PAM case reports varied but did not appear to be increasing over time. The fatality rate was approximately 95%.[135] However, in 2013, there were two pediatric survivors of PAM in the United States. One was a 12-year-old girl, one an 8-year-old boy. Both received similar treatment regimens, with the exception being that the 12-year-old girl was also managed with hypothermia. The 12-year-old girl who received the combination therapy and therapeutic hypothermia made a full neurologic recovery, whereas the 8-year-old boy, who was diagnosed and treatment begun several days after presentation, suffered permanent neurologic complications.[136]

Naegleria species typically cause PAM in children and healthy adults who have been swimming in infected water. *N. fowleri* enter through the olfactory neuroepithelium at the level of the cribriform plate and invade the submucosal nervous plexus. Symptoms begin after a 3- to 7-day incubation period. PAM presents in a manner similar to acute bacterial meningitis, but physicians often miss the diagnosis initially. History is vital for making the diagnosis. Recent exposure to diving, swimming, or splashing in warm freshwater should suggest the possibility of amebic meningoencephalitis. Prompt examination of the CSF for *N. fowleri* is fundamental to establishing this diagnosis. The onset of PAM is abrupt but nonspecific. Patients may complain of sore throat, headache, nausea, vomiting, malaise, and fever. Early findings may also include irritability, hallucinations, meningismus, cerebellar ataxia, and cranial nerve palsies, although focal neurologic defects are usually absent. Alterations in taste and smell may occur, likely due to involvement of the olfactory nerve.[137] Brain imaging should be obtained, but findings of CT and MR imaging may be normal early in the disease, with evidence of brain edema, basilar meningeal enhancement, and sometimes infarcts seen later in the disease process.[138]

Differential diagnosis for PAM includes acute bacterial meningitis, HSV-1 or other viral encephalitis, and fungal meningitis. With immunosuppressed patients, PAM might be confused with toxoplasmosis, CMV infection, and other opportunistic pathogens. The diagnosis is made by examination of centrifuged CSF wet mounts for motile trophozoites. However, failure to visualize these amebae does not exclude PAM. The diagnosis is often missed when *Naegleria* organisms are mistaken for atypical leukocytes, specifically monocytes or lymphocytes.[139]

PAM infections tend to be fulminant, with seizures progressing to coma and death within 4 to 6 days. Autopsy findings typically demonstrate acute hemorrhagic necrotizing meningoencephalitis with purulent exudates in the brain, brain stem, and cerebellum.

The extremely low incidence of PAM makes epidemiologic study difficult. Questions concerning why certain individuals become infected with the amebae while many others are exposed to the same freshwater sources remain. Attempts are

under way to determine what concentration of *N. fowleri* in the environment poses an unacceptable risk to swimmers, how a standard might be set to protect human health, and how regulators might measure and enforce such a standard.

The free-living amebas *Acanthamoeba* spp. and *Balamuthia mandrillaris* cause a subacute CNS infection, GAE. More so than the *Naegleria* organism, *Acanthamoeba* is ubiquitous in the environment, with amebas widely disseminated in soil and water. Unlike the healthy individuals acquiring *Naegleria* infections, *Acanthamoeba* infections of the CNS are typically in compromised hosts, such as those with AIDS, those with IgA deficiency, or those undergoing suppressive therapy for organ transplant or autoimmune diseases. However, cases in immunocompetent individuals have also been reported. Making this diagnosis requires a high index of suspicion, as it is easily confounded by potential manifestations of the underlying disease. The portal of entry of this species of ameba can vary. It may be intranasal, allowing amebas to migrate directly to the CNS, via a break in the skin or through the respiratory tract, with subsequent spread of amebas to the CNS by a hematogenous route. The disease assumes a chronic status, leading to slow deterioration. Gadolinium-enhanced TI-weighted MR images of the brain show multiple punctate focal areas of enhancement bilaterally throughout the cerebellar hemispheres, with some scattered foci supratentorially.[140] These lesions may represent focal cerebritis or microabscesses. Diagnosis is most often made by postmortem examination of brain tissue showing patchy, chronic granulomas encephalitis with trophozoites and cysts in the lesions. Brain biopsy, often required to make a definitive diagnosis, reveals numerous trophozoites with round nucleus, prominent nucleolus, and thin nuclear membrane. Methenamine silver stain shows encysted ameba. Specific serum antibodies may not be a reliable measure in immunocompromised patients, and trophozoites in CSF can be confused with monocytes.[141]

Based on the treatment regimens used in the most recent survivors of PAM, the CDC currently recommends the following drug therapy in CNS infections caused by *N. fowleri* as well as *B. mandrillaris* and *Acanthamoeba* species: (1) IV amphotericin B, (2) intrathecal amphotericin B, (3) azithromycin, (4) fluconazole, (5) rifampin, (6) miltefosine, and (7) dexamethasone. Miltefosine is an investigational drug previously used to treat breast cancer and leishmaniasis shown to have amebicidal activity against *Balamuthia, N. fowleri,* and *Acanthamoeba*.[142] The CDC has an investigational drug protocol (IND) in effect with the FDA to make miltefosine available directly from the CDC for the treatment of free-living amebas.[143,144] For diagnostic assistance, specimen collection guidance, shipping instructions, and treatment recommendations, clinicians are to contact the CDC Emergency Operations Center at (770) 488–7100.

Acute Disseminated Encephalomyelitis

Acute disseminated encephalomyelitis (ADEM) is an acute inflammatory demyelinating disorder of the central nervous system. Though it is not typically associated with primary CNS infection, patients with ADEM often have a preceding febrile illness (93%) or vaccination (5%) that is thought to trigger an autoimmune response.[145] The inflammatory response of ADEM may result in a clinical picture that is similar to infectious meningitis or encephalitis, and therefore advanced neuroimaging and an infectious workup are often performed. Population-based

epidemiologic studies have estimated that between 0.1 and 0.8/100,000 cases of ADEM occur in children annually, at a median age of 5 to 8 years.[145-147] Although ADEM may be diagnosed with mild symptoms such as headache and lethargy, children often present with more severe and progressive symptoms with up to 25% of cases requiring admission to a PICU.[148]

ADEM is an immune-mediated process likely triggered by antigenic stimulation. According to this hypothesis, called “molecular mimicry,” certain amino acid sequence homologies and antigenic epitopes are shared between an invading pathogen or inoculated vaccine and host CNS proteins such as myelin basic protein. Initially, the pathogenic material is processed at the site of infection or inoculation. The adaptive immune response causes T-cell activation and ultimately the production of antigen-specific B cells. If these cells encounter the homologous myelin protein, local reactivation and immune reaction against the presumed foreign antigen are elicited. Thus, a physiologic immune response causes autoimmunity distant from the original site of infection or inoculation. Histologically, the lesions of ADEM appear similar to those of patients with multiple sclerosis (MS), though ADEM can often be distinguished by the finding of perivenous demyelination of similar age as opposed to the more confluent demyelination and heterogeneous appearance characteristic of MS.[149] In patients with ADEM, demyelination may not be present in the acute lesion(s) but tends to develop later in the disease process, often in a sleevelike pattern confined to the area of inflammation. Damage to the axon itself is rare.

The combination of altered consciousness or behavior and multifocal neurologic deficits, especially in close relation to an infection or vaccination, should raise the clinician's suspicion of ADEM. Patients may present with nonspecific symptoms such as headache, vomiting, lethargy, and low-grade fever. Apart from neurologic findings, the remainder of the physical examination is most often normal. Distinct functional cognitive deficits are present in the majority of patients at the time of admission. Motor deficits and cranial neuropathies (particularly of extraocular movements) are the most common focal finding. Clinical deterioration and development of new neurologic deficits are prominent features in the hospital course of many patients with ADEM. When ICU management is needed, patients often require mechanical ventilation, typically due to brain stem involvement or severely impaired consciousness, with the median duration of mechanical ventilation of 3 days (Table 70.5).[148]

TABLE 70.5

Clinical Features of Children With Acute Disseminated Encephalomyelitis Requiring Intensive Care

Feature/Symptom	Prevalence (%)
Encephalopathy/encephalitis/encephalomyelitis	100
Multifocal neurologic deficit	22
Seizure	19
Mechanical ventilation (typically due to brain stem involvement or severely impaired consciousness)	78
Inotrope/vasopressors	15
Invasive intracranial pressure monitoring	4

Data from Absoud M, Parslow RC, Wassmer E, et al. Severe acute disseminated encephalomyelitis: a paediatric intensive care population-based study. Mult Scler. 2010;17: 1258-1261.

Specific laboratory criteria do not exist for the diagnosis of ADEM. Similar to other demyelinating conditions, patients with ADEM typically have increased levels of CSF protein and a mild lymphocytic CSF pleocytosis. In contrast to MS, oligoclonal bands are rarely detected.[150] EEG will often be abnormal and typically shows diffuse slowing consistent with encephalopathy. Focal lesions may be present on neuroimaging, but the finding of focal epileptiform activity is rare. A CT scan is often the initial neuroimaging study obtained to rule out conditions such as a space-occupying lesion or acute hydrocephalus. However, the radiologic study of choice to diagnose ADEM is an MRI of the brain and spinal cord. The T2-weighted and fluid-attenuated inversion recovery (FLAIR) sequences are most useful for identifying ADEM-associated lesions (Fig. 70.6). Although there is no lesion pattern pathognomonic for ADEM, they are most typically large (≥1–2 cm), asymmetric, poorly demarcated, and involve the subcortical and central white matter and the gray-white matter junction of the cerebral hemispheres, cerebellum, brain stem, and spinal cord. Gray matter involvement may be seen, particularly in the thalamus and basal ganglia. Using diffusion-weighted imaging (DWI) and apparent diffusion coefficient (ADC) maps, most patients will demonstrate vasogenic edema (increased signal intensity in both sequences), as opposed to cytotoxic edema.[151]

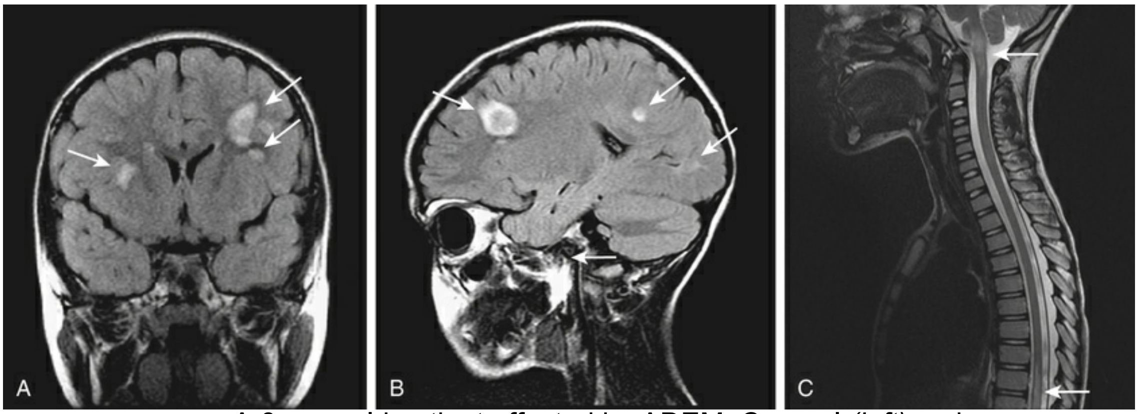

FIG. 70.6 A 6-year-old patient affected by ADEM. Coronal *(left)* and sagittal *(middle)* FLAIR images of the brain show confluent T2-FLAIR hyperintense lesions in the subcortical white matter of the cerebral hemispheres bilaterally *(arrows)*. Sagittal T2 image of the cervical and thoracic spine *(right)* shows medullary involvement extending from brain stem to cervical cord. Beginning at T8-9 disc space, there is another lesion with abnormal T2 signal *(arrows)*.

Given the presumed autoimmune pathogenesis of ADEM, high-dose corticosteroid therapy is the recommended first-line therapy. Typically, methylprednisolone 10 to 30 mg/kg/day is administered for 3 to 5 days, followed by an oral taper over 4 to 6 weeks.[146] A taper less than 4 weeks is associated with a greater risk of relapse. Of note, there are no randomized clinical trials of steroids for the treatment of ADEM. A retrospective study of 84 children comparing treatment with methylprednisolone to dexamethasone found improved disability scores in the children who received methylprednisolone. IVIG may be used, either alone or more commonly in combination with corticosteroids, at a dose of 2 g/kg divided over 2 to 5 days. In cases refractory to high-dose steroids, plasmapheresis has been shown to

have a 42% response rate. In fulminant cases with severe cerebral edema and elevated ICP, successful decompressive craniectomy has been reported in children.[152] Although relapses may occur, most children make a complete neurologic recovery within 6 months of the initial presentation. Patients with large or bithalamic lesions on MRI are more likely to have residual disability.[153]

Acute Hemorrhagic Leukoencephalitis

Acute hemorrhagic leukoencephalitis (AHLE) is a rare, and often fatal, demyelinating disorder of the CNS seen in adults and children. It is often considered to be a severe presentation on a spectrum of autoimmune demyelinating disorders with ADEM (Table 70.6). In each case, patients may have a history of recent illness or vaccination, they typically present with or develop alterations in mental status and multifocal neurologic deficits, and neuroimaging demonstrates large poorly demarcated areas of demyelination and edema. However, compared to ADEM, patients with AHLE typically have (1) higher CSF and peripheral leukocytosis with neutrophilic predominance, (2) elevated ICP, and (3) a rapidly progressive and often fatal course. Additionally, AHLE may be more common in young adults and patients of Asian or Pacific Island ancestry with several reported cases in patients of Filipino descent.[154,155]

TABLE 70.6

Clinical and Laboratory Features of Acute Disseminated Encephalomyelitis (ADEM) and Acute Hemorrhagic Leukoencephalitis (AHLE)

Feature	ADEM	AHLE
Rapidly progressive and fatal	3%	60%
Typical age	Children	Young adults
Prodromal illness or vaccination	Often	Often
CSF WBC, median (range), cell/uL	15 (0-340)	145 (2-11,900)
CSF protein, median (range), mg/dL	32 (14-672)	115 (12-1290)
Elevated CSF opening pressure or ICP	8%	71%
Peripheral WBC, median (range), cells/uL	13,000 (3300-28,100)	17,000 (15,000-40,000)
Pathologic features	Focal demyelination, perivascular neutrophilic infiltrates, hemorrhage absent	Focal demyelination, perivascular neutrophilic infiltrates, focal perivascular hemorrhage

Data from Leake JA, Billman GF, Nespeca MP, et al. Pediatric acute hemorrhagic leukoencephalitis: report of a surviving patient and review. Clin Infect Dis. 2002;34: 699-703.

Despite extensive clinical workup in most cases, the pathogenesis of AHLE remains unknown. Brain biopsy or autopsy from children with AHLE classically shows hemorrhagic perivascular demyelination, edema, and neutrophilic inflammatory infiltrates. Biopsies taken within the first 48 hours of symptom onset may not yet show demyelination. Instead, early biopsy may demonstrate widespread dystrophic astrocytes with swollen perivascular end feet. This suggests that demyelination in AHLE might be secondary to astrocyte injury similar to that observed in patients with neuromyelitis optica and central pontine myelinolysis.[156] Complement activation may have a role in the pathophysiology of AHLE. Two

patients with recurrent AHLE and a fulminant course were each found to have a significant decrease in complement inhibition. The patients had a genetic mutation in complement factor I gene that led to increased C3b, membrane attack complex deposition on neuronal cell surfaces, and interleukin-1β (IL-1β) mediated inflammation. A similar deficiency of complement inhibition is known to cause atypical hemolytic uremic syndrome. In addition to ICP-directed therapies, each patient received immunomodulatory treatment with high-dose corticosteroids, IVIG, and anakinra (IL-1 receptor antagonist). Anakinra was continued long term to prevent relapse, and each patient had a good functional outcome.[155]

Approximately 20 cases of pediatric AHLE have been reported, and overall mortality is ~50%.[157] The patients who have survived received ICP-directed therapy including hyperosmolar therapies and craniectomy, high-dose corticosteroids, and in some cases additional immunomodulatory therapies such as IVIG and anakinra. If possible, most clinicians will perform lumbar puncture to exclude active CNS infection prior to giving high-dose steroids. A lumbar puncture with elevated opening pressure, leukocytosis with neutrophilic predominance, and elevated CSF protein that may mimic a bacterial or fulminant herpetic infection may be seen in cases of AHLE. In this case, neuroimaging may be beneficial to limit delays in therapy if the characteristic large, multifocal, white matter AHLE lesions are observed.

Anti–N-Methyl-D-Aspartate Receptor−Mediated Encephalitis

In 2007, a case series was published of 12 women with prominent psychiatric symptoms, amnesia, dyskinesias, seizures, and autonomic dysfunction caused by antibodies to the N-terminal extracellular domain of the NR1 subunit of the NMDA receptor (NMDAR). These women all had ovarian or mediastinal teratoma, and resection of the tumor and immunotherapy proved curative.[158] More recent population-based studies have established anti-NMDAR encephalitis as the cause for many cases of idiopathic encephalitis and even diagnosed patients thought to have primary psychiatric disorders admitted to the ICU. For example, in epidemiologic studies from California, Australia, and the United Kingdom, 4% to 6% of patients with encephalitis have anti-NMDAR antibodies.[159-161] This finding makes anti-NMDAR encephalitis the second most common cause of immune-mediated encephalitis (behind ADEM), and four times more common than HSV-1, WNV, and VZV. Additional antigenic targets on the neuronal surface have been identified such as the voltage-gated potassium channel complex (VGKC), α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionic acid receptor, and glycine receptor, but apart from anti-VGKC encephalitis, these rarely cause illness in pediatric patients.

Anti-NMDAR antibodies act by decreasing the surface density and synaptic localization of NMDAR clusters, by mechanisms including antibody-mediated capping and internalization, without affecting other synaptic proteins or receptors.[162] The effect is dose-dependent–higher antibody titers that cause a greater decrease in NMDAR density, and a reduction of antibody titers reverses this effect. The loss of synaptic NMDARs impairs glutamatergic synaptic transmission and may cause the cognitive and behavioral changes characteristic of autoimmune encephalitis. In 55% of adults, anti-NMDAR antibodies are associated with a tumor, typically an ovarian

teratoma that contains nervous tissue and expresses NMDARs. In children, the presence of tumor is less common. Current theories suggest antigenic stimulation by infection or tumor that activates lymphocytes, disrupts the BBB, and allows clonal expansion of B cells within the CNS. The NMDAR antibodies can be detected in serum but are often higher in CSF, suggesting intrathecal antibody synthesis.[163]

The diagnosis of anti-NMDAR encephalitis is suggested by a characteristic clinical progression: prodrome of fever, headache, and gastrointestinal or respiratory symptoms followed by psychiatric and behavioral changes, language deficits, and seizures, progressing to dysautonomia, movement disorders, altered consciousness, and central hypoventilation. This pattern suggests an initial cortical disease process progressing to involve subcortical structures.[163] In children older than 12 years old, psychiatric or behavioral symptoms often present first; whereas children younger than 12 often present with new-onset seizures or movement disorder. Orofacial dyskinesias are characteristic and described as fish- or rabbit-like movements, although many other movements are described and can be self-injurious. The seizures of anti-NMDAR encephalitis can be difficult to diagnose and treat with traditional anti-epileptic drugs. One case report describes a woman who was in a nonconvulsive status epilepticus and pentobarbital coma for months before a prophylactic oophorectomy found a microscopic ovarian teratoma. The patient improved within a week following the procedure.[164] Many children with anti-NMDAR encephalitis will require critical care as symptoms progress to include autonomic instability, hypoventilation, and altered consciousness. Up to one-quarter of patients will require mechanical ventilation.

MRI is normal in 50% of patients with anti-NMDAR encephalitis, but it may show T2 signal intensity in the frontotemporal region, hippocampus, basal ganglia, brain stem, or spinal cord (Fig. 70.7). Initial lumbar puncture typically shows variable CSF lymphocytic pleocytosis, elevated protein, and oligoclonal bands. Clinical tests for NMDAR antibodies are available and should be sent from serum and CSF. Low serum titers should be interpreted cautiously and are not 100% specific. All patients should be tested for an underlying ovarian teratoma or testicular germ cell tumor, although other malignancies such as Hodgkin lymphoma and neuroblastoma, as well as infectious etiologies, have been associated with anti-NMDAR antibodies.[163]

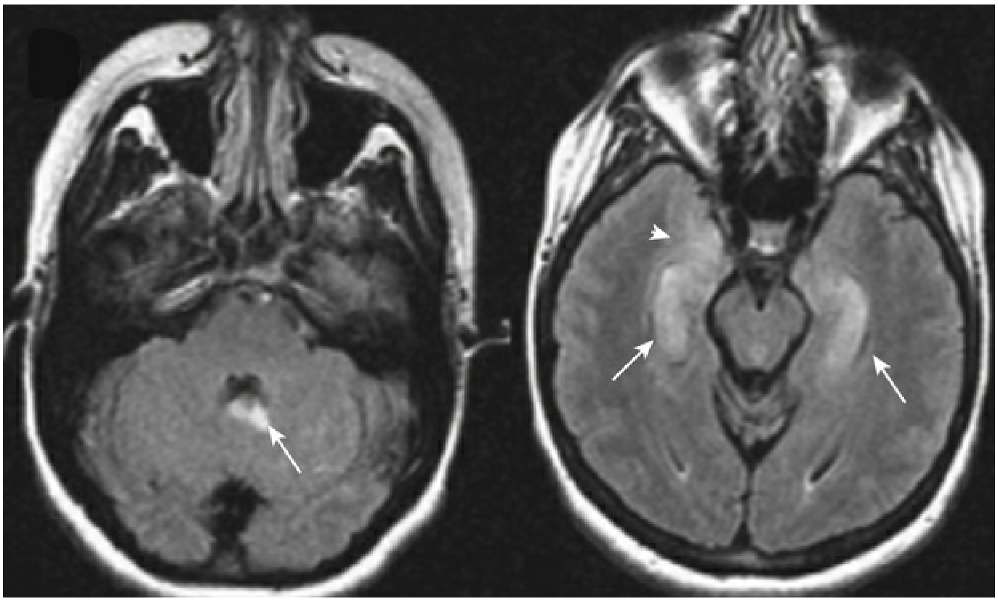

FIG. 70.7 A 26-year-old patient with anti-NMDAR encephalitis and ovarian teratoma. Axial T2-FLAIR images show increased signal in the cerebellar vermis *(left, arrow)*, bilateral hippocampus *(right, arrows)*, and right temporal uncus *(right, arrowhead).* (From Simon DW, Da Silva YS, Zuccoli G, et al. Acute encephalitis. Crit Care Clin. 2013;29:259-277.)

A large-multicenter cohort study of 577 patients with anti-NMDAR encephalitis (including 212 children) found that only 53% of patients responded to first-line therapy, including tumor removal or immunotherapy (steroids, IVIG, or plasma exchange). There were no differences according to age of the patient. Of patients who failed first-line therapy, treatment with second-line therapy (rituximab, cyclophosphamide) improved outcomes versus no additional therapy.[165] The strongest predictors of good outcome were early treatment (Fig. 70.8) and lack of ICU admission. Persistent deficits are more likely if a tumor is not detected, and they are primarily in executive function and memory, where NMDAR function is most influential.

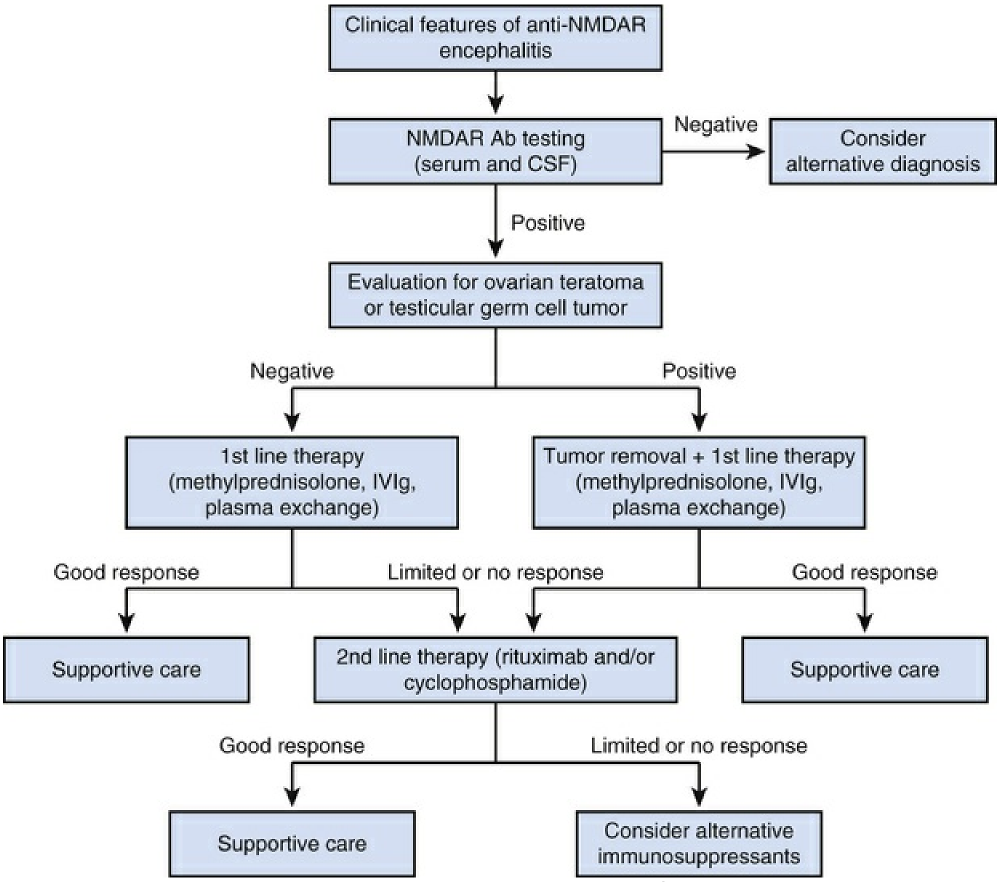

FIG. 70.8 Proposed treatment approach for anti-NMDAR encephalitis. (Adapted from Florence-Ryan N, Dalmau J. Update on anti-*N*-methyl-D-aspartate receptor encephalitis in children and adolescents. Curr Opin Pediatr. 2010;22:739-744.)

Central Nervous System Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis (HLH) is severe sepsis-like disease that primarily affects infants and young children. Caused by autosomal recessive mutation in the genes that control perforin and granzyme signaling required for natural killer and cytotoxic T-lymphocyte cytotoxicity (also called familial HLH, or fHLH), patients are unable to turn off the immune response leading to cytokine storm and multiorgan failure (see Chapter 112 for additional details). Postmortem studies have shown that CNS HLH has a large severity spectrum, with mild cases having a lymphocytic and macrophage infiltration of the meninges, to severe cases in which there is tissue infiltration and multifocal necrosis.[166] Hemophagocytosis was observed in most of the brains at all injury severity levels.

Neurologic symptoms are common and may even precede systemic symptoms of HLH. In these cases, distinguishing CNS HLH from primary CNS disorders such as meningitis and ADEM can be a challenge. Patients with fHLH commonly present with neurologic deficits or abnormal CSF values: 63% of children presenting with fHLH have neurologic symptoms and an additional 24% have abnormal findings on CSF analysis.[167] The presenting symptoms of CNS HLH include seizure (35%), impaired consciousness (31%), meningismus (31%), hypotonia (21%), motor deficit

(17%), and cranial nerve palsy (7%). CSF analysis typically shows only mild elevation in protein or leukocytosis. Similarly, half of the children with CNS HLH will have normal MRI findings early in the course. When changes are detected on MRI, in comparison to ADEM, they are more likely to be symmetric, periventricular, and involving a large area of the brain.[167] Patients presenting with neurologic findings or abnormal CSF have a greater risk of long-term neurologic sequelae and higher mortality rate than patients without neurologic features and normal CSF.

Treatment of fHLH is guided by the HLH-2004 protocol.[168] In children with persistent symptoms of CNS involvement despite systemic chemotherapy, intrathecal chemotherapy (often methotrexate) is often added. Dexamethasone, which has better BBB penetration than other systemic corticosteroids, is often used in place of methylprednisolone or prednisone. Perhaps the best way to reduce long-term neurologic deficits is hematopoietic stem cell transplant (HSCT) once remission is obtained.[169] Unfortunately, despite significant improvements since the 1990s in the treatment of patients with fHLH using multimodal chemotherapy and HSCT, outcomes for patients with CNS HLH remain poor with greater than 25% mortality and 60% long-term neurologic sequelae (27% with severe deficits).

Conclusion

CNS infectious and parainfectious diseases represent an important cause of mortality among PICU patients. Prompt recognition of CNS disease is essential in order for the intensivist to initiate specific medical and surgical treatment. Although the lack of specific therapy for many viral causes of meningoencephalitis remains frustrating, appropriate supportive care can improve mortality and functional outcomes for all patients with CNS infections and related conditions.

CHAPTER 71

Acute Neuromuscular Diseases and Disorders

Ann H. Tilton

PEARLS

- Common causes of acute flaccid paralysis in childhood include Guillain-Barré syndrome (GBS), botulism, tick paralysis, periodic paralyses, and organophosphate poisoning.
- Risk factors for respiratory failure in GBS include elevated cerebrospinal fluid protein in first week of disease, short time interval between prodrome and onset of GBS symptoms, cranial nerve involvement, myasthenia gravis symptoms, ptosis, diplopia, pupillary sparing, and weakness that waxes and wanes.
- Asbury criteria for GBS include required criteria, namely progressive motor weakness of more than one limb and areflexia, and supportive criteria, namely symmetry of symptoms, mild sensory changes, cranial nerve involvement, and autonomic symptoms. Recovery begins 2 to 4 weeks after symptom progression discontinues.
- Classic botulism symptoms include weak cry, poor suck and swallow, decreased tone, decreased reflexes, weakness in descending pattern, constipation, and autonomic symptoms especially tachycardia and fluctuating blood pressure, urinary retention, decreased tears and saliva, and flushed skin or pallor.

Neuromuscular diseases that encompass the entire motor unit may have similar presentations initially and must be deciphered in a methodical manner. The motor unit consists of the anterior horn cell, which is located in the spinal cord and terminates in a motor nerve; the myelin associated with the nerve; the neuromuscular junction; and the muscle that the nerve innervates. Any disruption of function in this pathway may produce weakness of some variety. Neuropathies and myopathies have similar clinical findings, including weakness and decreased or absent reflexes. These disease processes may be distinguished, however, by sensory abnormalities and the distribution of the weakness. Neuromuscular junction defects may have reflexes present, as in myasthenia gravis, or absent, as seen in tick paralysis. The clinician can narrow the etiologic possibilities by considering the

clinical presentation, family history, recent illness, travel, inciting factors, and the clinical course.

This chapter is devoted to acute neuromuscular diseases that present to a pediatric intensive care unit. Although clinicians may encounter a variety of neuromuscular illnesses, this chapter begins with the most common disorders presenting to the pediatric intensive care unit. Weakness due to spinal cord or other central nervous system abnormalities is discussed in a separate chapter.

Guillain-Barré Syndrome

The most common acute neuromuscular disease to present to the intensive care unit is Guillain-Barré syndrome (GBS). When given the history of an ascending paralysis, a clinician can easily place GBS in the differential diagnosis; however, this history may be difficult to obtain, particularly if the patient is a small child or an infant. GBS is the most common cause of acute flaccid paralysis in children with an incidence estimated to be 0.38 to 1.1 per 100,000 in a population younger than 15 years.[1,2] A prodromal respiratory or gastrointestinal illness is commonly reported. These illnesses may include *Campylobacter jejuni* and cytomegalovirus (CMV). In one study, 70% of patients reported an illness before the onset of symptoms with 26% having documented CMV.[3]

The neurologic symptoms typically present with progressive paralysis that is relatively symmetric and may evolve to all extremities. Other symptoms include varying degrees of hyporeflexia or areflexia or even respiratory embarrassment. Presentations may include acute ataxia, pain, or cranial neuropathies.[4,5] Of note, pain is often a major complaint in the young child and makes the examination difficult. In one study, risk factors for patients requiring ventilation included cranial nerve involvement, elevated cerebrospinal fluid (CSF) protein during the first week of illness, and a short period between antecedent illness and onset of symptoms.[6] Autonomic symptoms may be overlooked. Autonomic instability, particularly cardiac arrhythmias, increases the morbidity of this disease. Cardiac monitoring of the R-R interval with reduction of beat-to-beat variability may possibly identify patients at risk for fatal arrhythmia.[7] Cardiac arrhythmias induced by tracheal tube manipulation have been reported.[8]

Symptoms that are strongly supportive of GBS include the relative symmetry of symptoms, mild sensory symptoms, cranial nerve involvement, autonomic symptoms, and recovery that usually begins 2 to 4 weeks after symptom progression discontinues. Sphincter disturbances rarely occur early in the course of GBS and are usually transient.[9,10]

Diagnostic studies include examination of the CSF and nerve conduction studies. The CSF reveals elevated protein (>45 mg/dL) amid a relative paucity of white blood cells (WBCs), usually less than 10 cells/mL with the protein increasing after the first week of symptoms.[9] Electrodiagnostic testing reveals motor conduction velocities in the demyelinating range, conduction block, temporal dispersion, and prolonged F waves. Bradshaw and Jones[4] reported that conduction block and temporal dispersion occurred in 74% of the patients.

It is important to recognize that the patients may need an intensive care setting. Criteria for ICU care include rapidly advancing weakness, flaccid quadriparesis, bulbar symptoms, vital capacity less than 20 mL/kg, and autonomic instability

(cardiac).[10] If the symptoms are severe, treatment options for GBS primarily include plasmapheresis and intravenous immunoglobulin (IVIG). Based predominantly on adult literature, the American Academy of Neurology has published practice guidelines providing treatment recommendations.[11,12] First, plasmapheresis and IVIG both hasten recovery, and neither is more efficacious. Using these two treatments sequentially is not superior to either treatment alone. Finally, steroids do not seem to help.[13] The decision of which therapy to apply to children is controversial because no large randomized study has yet been performed. Plasmapheresis may be technically difficult in young or very small children; therefore immunoglobulin is often used as the first choice. Favorable improvement in pediatric patients treated with immunoglobulin has been reported in several small series and on Cochrane review.[14-17] A randomized trial in children showed that fewer relapses occurred if 2 g/kg of IVIG were divided over 5 days instead of 2 days.[17] If additional courses of IVIG are necessary, a 2-day protocol is often well tolerated.

Several GBS variants exist. The best known are the Miller-Fisher variant and acute inflammatory axonal polyneuropathy, the axonal form of GBS. The neurologic triad found in the Miller-Fisher syndrome includes ataxia, areflexia, and ophthalmoparesis. Miller-Fisher syndrome has been linked to immunoglobulin G (IgG) antibodies against ganglioside GQ1b.[18] In some *C. jejuni* strains, molecular mimicry exists between the surface epitopes and ganglioside GQ1b.[19] The GQ1b ganglioside is thought to cross-react in the brain stem area of the ophthalmic cranial nerves.[20] The axonal form of GBS has been associated with a more prolonged recovery than the classic form of GBS due to axonal involvement. Early research suggests that CSF levels of neurofilament correspond to levels of axonal damage on electromyography (EMG) testing and may complement EMG studies to help predict patients with more prolonged recoveries.[21,22]

Myasthenia Gravis

Myasthenia gravis (MG) has many forms that may present in the pediatric population. The juvenile form of MG is the most common and is clinically identical to the autoimmune adult form of MG. Overall, however, juvenile MG is rare and constitutes 10% of all cases of MG in Western populations. Antibodies directed toward the acetylcholine receptor (AchR) at the postsynaptic neuromuscular junction cause this form of the disease. These antibodies result in blockade of the AchR, increase the degradation of the AchR, and also result in complement damage to the AchR.[23] AchR antibodies are found less frequently in juvenile MG compared with adult autoimmune MG and are more easily demonstrated in the postpubertal patient population.[24] Anticholinesterase antibody levels should be drawn, however, in all patients with suspected MG. Newer assays are identifying antibodies previously missed in older anticholinesterase antibody assays, including binding, blocking, and modulating antibodies, but these may need to be ordered separately.[25-27]

The most common heralding symptoms of weakness in MG include ptosis (with pupillary sparing) and diplopia from restricted eye movements. These symptoms wax and wane, and the weakness may generalize to the extremities. The two clinical forms of juvenile MG are ocular and generalized. In ocular MG, symptoms include ptosis and diplopia, but the weakness does not progress to other areas of the body.

Generalized MG may begin with ocular symptoms and progress to generalized weakness, usually within 1 year of onset; however, generalized weakness may be the initial presentation. As in adults with MG, pediatric patients have fewer symptoms in the morning or after rest. Increasing fatigability with exercise is an important hallmark of this disorder. The most troublesome symptoms in generalized MG are those involving bulbar muscles (difficulty chewing and swallowing), respiratory muscles, and exercise intolerance.

When a patient is suspected to have MG, the classic diagnostic bedside test is the edrophonium (Tensilon) challenge. Edrophonium is an intravenous short-acting anticholinesterase preparation that has limited availability in many hospitals. The dosing in infants is 0.15 mg/kg and 0.20 mg/kg in older children. Only 10% of the entire dose is given initially so that the clinician can observe for muscarinic side effects. Atropine (0.015 to 0.040 mg/kg) should be available for these possible side effects, which include bradycardia and respiratory distress secondary to bronchial secretions and bronchospasm. After the trial dose is tolerated, the entire dose is then given. In lieu of edrophonium, neostigmine is given at a dose of 0.025 to 0.050 mg/kg intramuscularly (IM). The patient should be observed during the trial for changes in ptosis or fatigability. The onset of action with edrophonium is approximately 30 to 90 seconds after intravenous delivery and remains for approximately 5 minutes. Neostigmine has an onset of action within 15 minutes, and effects may last for 1 hour. Many clinicians also perform a blinded placebo trial of normal saline.

The neurodiagnostic study used in patients with suspected MG is repetitive nerve stimulation. This study is best performed on proximal muscles, although distal muscles are often studied. The confirmatory finding on repetitive nerve stimulation is a 10% decrement in amplitude of the compound muscle action potential.

Antibodies have been found that can block, bind, or modulate AChR. Approximately 80% of patients will have antibodies to AChR found in standard assays. Antibodies directed against muscle specific kinase (MuSK) appear to account for some of the remaining 20%.[25] Newer, more sensitive assays can also identify antibodies with low affinity for AChR.[27] Clinically, MuSK-positive patients tend to have more frequent bulbar involvement and respiratory crises than AChR-positive patients and require larger doses of maintenance corticosteroids, though there is no clear difference in clinical outcomes.[28] Seronegative (AChR-negative and MuSK-negative) patients have a disease severity between the other two groups but appear to have better clinical outcomes.[28]

Treatment of MG begins with anticholinesterase medications. The symptoms of MG usually respond to pyridostigmine bromide (Mestinon), the most common oral form of anticholinesterase medication. The dosage of pyridostigmine bromide is 7 mg/kg per day divided four to six times daily as needed for symptoms. Immunosuppressant agents, including prednisone, azathioprine, cyclophosphamide, tacrolimus, and rituximab, may be added to the regimen for pyridostigmine nonresponders.[29] Mycophenolate mofetil may also be prescribed, though it has not proved more efficacious than placebo in two randomized trials of patients already on prednisone.[30-32] However, a subsequent study with an extended outcome duration, >25 months compared to 9 months in the previously mentioned studies, demonstrated that mycophenolate mofetil might be effective as either adjunctive therapy with prednisone or monotherapy, but maximum results may not be seen for greater than a year.[30] Prednisone is usually initiated at 1 to 2 mg/kg per day.

Clinicians must be careful with the use of prednisone because it may exacerbate weakness on initiation.

Many studies have suggested that beneficial effects of thymectomy are best when performed early in the course of MG.[24,33,34] Because of the spontaneous remission rate reported by Rodriquez and colleagues as 22.4 per 1000 person-years, however, many clinicians are reluctant to proceed with early thymectomy, particularly with young children.[35]

Myasthenic crisis is an exacerbation of myasthenic symptoms requiring ventilatory assistance. In adult MG, myasthenic crisis has been reported to occur in 15% to 20% of patients, with 74% having their first crisis within 2 years of disease presentation.[36,37] Anlar and coworkers reported that one-third of patients with juvenile MG had at least one episode of crisis.[38] Initial therapy during crisis includes mechanical ventilation, which provides rest for the weakened patient.

Anticholinesterase medications should be discontinued during a crisis because they increase secretions that could lead to mucous plugging. Myasthenic crisis is most commonly heralded by infection in 38% of patients; however, 30% of patients have no obvious trigger for their crisis other than respiratory or bulbar weakness.[37] A thorough investigation for the cause of crisis should be undertaken.

Plasmapheresis and IVIG (2 g/kg over 2 to 5 days) also play a role in the treatment of myasthenic crisis and acute exacerbation of myasthenic symptoms. In adult crisis, plasmapheresis has been shown to be more efficacious than IVIG; however, plasmapheresis has more deleterious side effects, including cardiovascular and infectious complications.[39] IVIG has been shown superior to placebo in a randomized controlled trial with significant improvements seen as early as 14 days after infusion and lasting through 28 days.[40] Evidence supports the use of IVIG for treatment in myasthenic crisis or exacerbation in patients for whom plasmapheresis is not feasible.

Cholinergic crisis must also be a consideration in a patient with an MG exacerbation. Cholinergic crisis occurs with an overdose of anticholinesterase drugs in patients with MG. The overdose causes depolarization of skeletal muscles and muscarinic side effects, including increased secretions, diarrhea, lacrimation, sweating, and bradycardia. These symptoms will improve on withdrawal of the anticholinesterase medications. Some authors argue that cholinergic crisis is rarely the cause for worsening myasthenic symptoms.[36,41]

The clinician must always be cautious when initiating new medications in the patient with MG. Many drugs interfere with the neuromuscular junction; the best known are the aminoglycoside medications. Although not well recognized, steroids can also exacerbate weakness in a patient with MG. For this reason, one must be cautious when beginning prednisone in the patient with refractory MG, observing closely for any initial increased weakness. Other antibiotics that have been implicated in the worsening of myasthenic symptoms include ampicillin, ciprofloxacin, clindamycin, erythromycin, sulfonamide, tetracycline, and the peptide antibiotics (polymyxin A and B and colistin). Cardiovascular medications including the antiarrhythmics (quinidine, procainamide, and lidocaine) and beta-blockers have also been reported to worsen symptoms. Thyroid replacement medications and phenytoin may also cause problems. The neuromuscular junction blockers, including vecuronium, rocuronium, and pancuronium, as well as succinylcholine, should be used with caution because the effects of these medications are prolonged in patients

with MG.[41,42] On its website at www.myasthenia.org, the Myasthenia Gravis Foundation of America maintains a list of medications to avoid and to use with caution.

Additional immune diseases have been associated in approximately 16% of patients with juvenile MG.[35] The autoimmune diseases may include asthma, rheumatoid arthritis, juvenile diabetes mellitus, hyperthyroidism, chronic inflammatory demyelinating polyneuropathy, and CNS demyelination.[35,43,44] Seizures have also occurred in 4% to 12% of patients with juvenile MG, although the exact cause is not known.[35]

Congenital and Transient Neonatal Myasthenia Gravis

The other forms of MG are congenital MG and neonatal transient MG. Neonatal transient MG is unique in neonates who are born to mothers with autoimmune MG. Neonates can manifest symptoms of neonatal transient MG even if the mothers were symptom free during pregnancy and delivery. Neonatal transient MG occurs in approximately 12% of infants born to mothers with MG.[45] If a mother with MG gives birth to an infant with neonatal MG, her subsequent neonates are also at increased risk of having this transient disorder. Neonatal MG usually resolves in the first few weeks after birth, when the maternally derived antibody level diminishes in the neonate. Results from several studies have shown that even symptom-free infants born to mothers with MG have elevated titers of AchR antibodies.[46] Additionally, the same phenomenon has been reported in infants born to mothers with anti-MuSK.[38] The antibody concentration of the symptom-free neonate rapidly decreases when compared with the antibody concentration of a neonate with symptoms.[47] The symptoms of neonatal transient MG usually include hypotonia, feeding problems (particularly fatigue), weak cry, and respiratory difficulty. The treatment of these symptoms is supportive, with anticholinesterase medications used for severe symptoms.

Congenital MG usually presents in childhood, with symptoms similar to those of juvenile MG. Many defects are responsible for causing symptoms in congenital MG, including congenital abnormalities resulting in presynaptic, synaptic, or postsynaptic defects of the neuromuscular junction.[48] Congenital MG is always negative for Ach antibody, and a family history of congenital MG may or may not be present. The inheritance of congenital MG may be autosomal recessive or dominant or sporadic.[48] Treatment of congenital MG is different from the treatment of juvenile MG because immunosuppression obviously does not play a role. Symptoms of congenital MG may or may not respond to anticholinesterase medications.

Tick Paralysis

The clinician must always entertain tick paralysis in the differential diagnosis of acute flaccid paralysis in children. On presentation, patients with tick paralysis may be mistakenly diagnosed with GBS. The treatment of the two diseases is distinct; therefore, a high index of suspicion for tick paralysis should be maintained.

Affected patients are usually between the ages of 1 and 5 years. A review of 33

patients with tick paralysis reported 82% were younger than age 10 years, and 76% were female.[49] Longer hairstyles have been speculated to be the cause of this female preponderance. A thorough search of the patient should ensue because more than one tick may be attached. The ticks most commonly implicated in North America are *Dermacentor andersoni* (wood tick) and *Dermacentor variabilis* (dog tick); however, other types of ticks have also been documented.[50] In Australia, the most common tick variety to cause paralysis is *Ixodes holocyclus*.[50] The cause of the weakness is a neurotoxin that is secreted in the saliva of the gravid female tick. The neurotoxin is produced during the engorgement phase of feeding after mating. The neurotoxin inhibits the release of acetylcholine at the presynaptic terminal.[50]

The symptoms in North American hosts begin with vague complaints of fatigue, irritability, and pain. Vague symptoms may not begin until approximately 5 days after tick attachment, but they progress rapidly.[51] Symptoms may also include cerebellar signs, such as ataxia.[51] If the tick remains attached, a symmetric ascending flaccid paralysis with areflexia develops. Subsequently, bulbar and facial weakness as well as respiratory involvement occur. No systemic features are seen in tick paralysis. Patients are afebrile with normal vital signs, erythrocyte sedimentation rate (ESR), CSF, and mental status. The removal of the tick rapidly reverses symptoms, usually within 24 hours.

On discovery, the tick needs to be promptly removed. The tick is removed with blunt curved forceps or tweezers. The tick should be grasped at the point of attachment, as close to the skin as possible. The tick should be pulled upward with steady pressure. Twisting or jerking motions may cause parts of the tick to break off, particularly the mouthparts. The tick should not be handled with bare hands. Needham[52] evaluated various methods of tick removal including fingernail polish, petroleum jelly, 70% isopropyl alcohol, and a hot kitchen match. None of these passive techniques induced tick detachment.

Tick paralysis is more severe in Australia than in North America. The presenting symptoms are similar to those in the North American cases; however, ocular involvement with nonreactive pupils has been described.[53] Flaccid paralysis may take days to evolve, unlike in North American hosts. The major difference in Australian tick paralysis occurs after the tick is removed. Australian patients must be carefully observed because maximal weakness may not occur until 48 hours after tick removal.[53]

Periodic Paralyses

Clinicians may encounter various forms of periodic paralysis (PP), including hypokalemic and hyperkalemic. Most forms of the periodic paralyses have a family history of the disease. The weakness, that eventually results in paralysis, is associated with potassium response as demonstrated in hyperkalemic PP or potassium serum levels in hypokalemic PP. Periodic paralysis may also be accompanied by abnormal cardiac rhythms including prolonged QT, as in Andersen-Tawil syndrome; checking an electrocardiogram may be prudent, regardless of the serum potassium level.[54] Andersen-Tawil consists of a triad of ventricular dysrhythmia, periodic paralysis, and dysmorphic features.[55]

Hypokalemic Periodic Paralysis

Hypokalemic periodic paralysis (HypoPP) is the most common form of the periodic paralyses. The presentation of HypoPP usually occurs within the second decade of life. The number of attacks, which may be frequent, usually decreases as patients get older. Occurrence of HypoPP is 1 in 100,000 people. The inheritance pattern of HypoPP is autosomal dominant with males more frequently affected, but one-third of cases are sporadic.[56] The most common mutation in familial HypoPP is the dihydropyridine receptor in the voltage sensitive Ca^{++} channel, located on chromosome 1q.[57] Another common mutation is a voltage-sensitive sodium channel, SCN4A.[56,58,59] In a minority of cases no mutation is found.[59,60]

The onset of symptoms in HypoPP usually occurs after the consumption of a high-carbohydrate meal or after vigorous exercise followed by rest. Other provoking factors include cold temperature, emotional stress, menses, and pregnancy. Weakness usually begins during sleep with the patient noticing weakness on awakening; initially the weakness is proximal in the legs then progresses distally before involvement in the upper extremities. It may progress to flaccid paralysis of all limbs with areflexia and normal sensation. Cranial nerve function remains normal with swallowing and respiratory function rarely affected. The patient remains alert with a normal mental status during the attack, and sensation remains intact. Weakness typically lasts a few hours but may last several days. On noticing the initial symptoms of mild muscle cramping or heaviness, some patients are able to abort an attack with light exercise.[60,61] Sudden death from cardiac arrhythmias or respiratory failure has been reported.[61-63] During paralytic attacks, patients have minimal urine output with decreased potassium excretion and absent defecation.[60,64] In HypoPP, myotonia confined to the eyelids has been described.[65] Before this report, myotonia was described as occurring only with hyperkalemic periodic paralysis.

Diagnosis of HypoPP can be confirmed with the identification of hypokalemia during an attack. Laboratory testing during HypoPP reveals a markedly diminished potassium level. Although serum potassium levels are decreased, the total body amount of potassium remains normal. The decreased potassium level is due to a shift of the potassium into the muscle cells, resulting in inexcitable muscle cells.[66] During an attack, potassium levels usually fall below 3, but levels below 2 have been reported.[67] Secondary causes of hypokalemia such as Bartter syndrome, corticosteroids, diuretics, hyperaldosteronism, laxatives, licorice, renal tubular acidosis, amphotericin B, p-aminosalicylic acid, alcoholism, and villous adenoma must be ruled out.[68]

The paralytic attack may be reversed with normalization of the potassium level. The clinician must be careful when correcting the potassium level, remembering that the total body amount of potassium remains normal. Correction with oral potassium (0.2 to 0.4 mmol/kg every 15 to 30 minutes) should be considered. Patients with cardiac symptoms or an inability to swallow, however, require parental potassium.[55] While the potassium level is corrected, vigilant cardiac monitoring, serial potassium levels, and muscle strength examinations should be used. Intravenous fluids with dextrose or physiologic saline should be avoided because they may prolong an attack or even induce cardiac arrhythmias.[68,69] Griggs, Resnick, and Engel [68] reported that 5% mannitol solution should be considered as a diluent for intravenous potassium replacement.

Links and colleagues[60] studied a large kindred with HypoPP and showed that all family members older than 50 years had permanent muscle weakness. The authors concluded that although all patients eventually exhibit permanent muscle weakness, only 60% may have paralytic attacks.

Once a patient is known to have HypoPP, prophylactic medications should be initiated. Acetazolamide has been shown to prevent future attacks in patients with and without a family history of the disease when they take daily doses of 250 to 750 mg.[70] Some patients, however, have been reported to have an exacerbation of attacks when taking acetazolamide.[71] Another report revealed acetazolamide prophylaxis improved strength between attacks in 80% of patients who displayed persistent weakness between paralytic attacks.[70] Daily oral potassium chloride does shorten the duration of the attacks but does not appear to prevent attacks.[70] Other medications used for prophylaxis of attacks include triamterene and spironolactone in patients not responsive to acetazolamide.[70,71] Considerations for the prevention of attacks include avoidance of high-sodium, high-carbohydrate meals, prolonged rest, and arduous exercise.

Thyrotoxic periodic paralysis is another entity of weakness with concomitant hypokalemia. As the name implies, a thyrotoxic state is the impetus of this disease. It is mostly found in adult Asian males, although it has been reported in the Asian-American pediatric population.[72] The purpose of treatment of this disease is to alleviate the hyperthyroid state (see also Chapter 85).

Hyperkalemic Periodic Paralysis

The term *hyperkalemic periodic paralysis (HyperPP)* may be misleading because high, normal, and low levels of potassium have been reported in these attacks.[73] The name *HyperPP* actually correlates to the response these patients have to potassium. HyperPP is also referred to as potassium-sensitive PP, which may be more appropriate and less confusing. HyperPP is autosomal dominant with a common gene located on chromosome 17q affecting the alpha subunit of the sodium channel, but other sodium channels may also be affected.[56,74,75] Sporadic cases have also been reported.[56,76] HyperPP usually presents in the first decade of life.

Rest after exercise is the most common provoking feature. Other provoking factors include cold temperatures and meal skipping. The pattern of weakness is similar to that for HypoPP: The legs are usually affected before the arms, with symmetric weakness. Weakness during the attacks varies from mild to flaccid quadriplegia with areflexia, but respiratory weakness rarely occurs. The sensory examination is normal. The length of attacks is typically shorter than that of HypoPP attacks, usually resolving in a few hours, but may persist for days. Myotonia and Chvostek sign are often found in these patients.

Attacks may be provoked by potassium intake and relieved by glucose intake. Light exercise can prevent an attack. Most attacks do not require treatment. In the rare severe attack, intravenous glucose, thiazides, acetazolamide, and beta-adrenergics can be used.[77] Cardiac monitoring is important if medical intervention is needed because cardiac arrhythmias may occur.[78] Prophylactic therapy should be considered in these patients because permanent muscle weakness does develop over time.[79] Acetazolamide and thiazides have also been used for prophylaxis of this disease.[80]

Botulism

Infantile botulism is a syndrome predominately found in infants 6 days to 12 months of age.[81] In infantile botulism, *Clostridium botulinum* enters the body as a spore through ingestion, germination occurs, and the organism begins to produce the neurotoxin that is the cause of the symptoms.[82] It differs from food-borne botulism, in which the preformed toxin is actually ingested. In mouse models, the relationship of the gut and the spores is important, with the pH of the gut and the transient lack of competitive intestinal flora being essential in allowing the spores to germinate.[81] Infants appear to be susceptible, as are adults who have abnormal intestinal flora from abdominal surgery, gut abnormalities, or antibiotic use.[83-86]

Most cases of infantile botulism occur in California, Pennsylvania, and Utah. In one report, more than 75% of the patients with botulism had *C. botulinum* in their home environment.[87] Other sources include soil disruption from cultivation or construction and parental occupations that involve soil exposure.[88] The consumption of honey and corn syrup is a risk factor. Children younger than 12 months should not be fed these products. The disease modifying role of breast-feeding remains controversial.[89,90]

The botulinum toxin irreversibly binds at the presynaptic segment of the neuromuscular junction, inhibiting acetylcholine release and causing neuromuscular weakness. The autonomic system is also affected because the toxin binds the acetylcholine-mediated preganglionic parasympathetic and sympathetic synapses, as well as the postganglionic parasympathetic synapse.[91]

The most common symptoms include weak cry, poor suck and feeding, decreased tone with decreased reflexes, weakness in a descending pattern, and constipation.[91] Autonomic symptoms, often the first to appear, include constipation, tachycardia, fluctuating blood pressure, urinary retention, decreased tears and saliva, and flushed skin or pallor.[81,92] L'Hommedieu and Polin[92] proposed an algorithm of symptoms beginning with tachycardia and constipation progressing to loss of head control, difficulty feeding, and weak cry. A depressed gag reflex is followed by peripheral muscle weakness and, finally, diaphragmatic weakness. Because of the combination of autonomic and neuromuscular symptoms, the infant with botulism may be mistaken to be septic or dehydrated. Enlarged, sluggishly reactive pupils may also be present but are less common than the other autonomic symptoms.[93]

The most concerning consequence of botulism is respiratory embarrassment. Schreiner, Field, and Ruddy[91] reported only 24% of the patients reviewed did not require ventilation or an artificial airway. Patients with botulism have also become apneic during certain procedures, including lumbar puncture and intravenous catheter placement.[91] Hypoxic ischemic encephalopathy resulting from respiratory arrest has been described, as well as syndromes of inappropriate secretion of antidiuretic hormone (SIADH), urinary tract infections, pneumonia, and autonomic instability.[91,93] Aminoglycosides exacerbate the neuromuscular blockade and should be avoided in botulism.[94]

The diagnosis of botulism is clinical but confirmed by isolation of the organism or toxin in stool. EMG in patients with botulism reveals decreased compound motor action potential (CMAP) amplitude and facilitation of the CMAP amplitude with high-frequency repetitive motor nerve stimulation.[95]

The management of patients with botulism has advanced. Previously, clinicians

could offer only supportive care until axonal sprouting could reestablish the neuromuscular junction. The median length of hospital stay was 27 to 37 days, and patients typically required mechanical ventilation for a median of 13 to 16 days.[87,93,96] In respiratory compromise, mechanical ventilation should be instituted until the patient regains protective reflexes and respiratory strength. If patients are unable to tolerate oral feeds, nasogastric or nasojejunal feeding should be initiated. Human botulism immune globulin (BIG) has provided the first direct pharmacologic treatment. A randomized, controlled trial has shown that BIG decreased mean hospital stay (5.7 weeks to 2.6 weeks), mean duration of mechanical ventilation, mean duration of feeding through tube or IV, and mean hospital charges with no adverse effects related to BIG.[97] A retrospective article spanning 30 years complemented the randomized trial.[98] Resolution of symptoms occurs in the reverse pattern of presentation, with return of head control appearing to be a reliable measure of improving muscle function.[92]

Diphtheria

Although diphtheria was the leading killer of children in the early 20th century, the United States currently reports fewer than 10 cases of diphtheria annually. Epidemics still occur in developed and developing countries.[99-100]

The most common form of diphtheria in children is the upper respiratory tract infection. Initial mild infection of the pharynx is followed by tonsillar pseudomembrane formation. The pseudomembrane consists of necrotic epithelium, fibrin, and numerous bacterial colonies, covering the airways and pharynx to the main bronchi down into the smaller bronchi. It can lead to aspiration and complete obstruction of the airway. Extensive soft tissue edema and lymph node enlargement occur.[99-101]

Toxic cardiomyopathy is estimated to occur in 10% to 25% of patients and is responsible for 50% to 60% of deaths.[102] It often arises in the second to third week of illness when the affected individual appears to be clinically improving. Abnormalities of the myocardium, the conductive system, and the pericardium occur. The conductive disturbances are in response to the toxin.[103] Cardiac ectopy is 100% sensitive and specific to predict fatal outcome in children with severe diphtheria.[102]

When there is severe disease, neuropathy is seen in approximately three-fourths of the patients.[99,101] In a classic case of diphtheria, local paralysis of the soft palate occurs 2 to 3 weeks after the beginning of the oropharyngeal infection. Weaknesses of the pharyngeal, facial, and ocular nerves follow. The symmetric polyneuropathy occurs in a stocking-glove distribution and begins between 10 days to 3 months following the oropharyngeal infection.[99,101,102]

The distal ascending weakness and spinal fluid findings may be indistinguishable from GBS.[102] Additionally, rare cases can have dysfunction of the autonomic function with associated hypertension and cardiac failure. Typically, there is complete recovery.

Diagnostically, cultures should be obtained from the nose, throat, and the infected mucocutaneous area. Giving the antitoxin is critical even if the diagnosis is only presumptive. If the antitoxin is administered on the first day, the mortality is 1% compared with a mortality of 20% if administration is delayed until the fourth day.[102]

Immunoglobulin preparations have also been hypothesized as helpful. The only antimicrobials that have had prospective studies proving efficacy are penicillin and erythromycin.[102]

One should anticipate airway complications, congestive heart failure, and malnutrition. Studies have revealed no difference in the occurrence of carditis, neuritis, or death in those receiving steroids. Digitalis is associated with an increased occurrence of arrhythmias. Overall prognosis depends on multiple variables, including the delay in the administration of the antitoxin, immunization status, and age. The mortality rate of 10% for respiratory tract diphtheria has not changed since the 1960s.[102]

Acute Intermittent Porphyria

The most common of the four types of porphyria is acute intermittent porphyria (AIP). Clinical symptoms in acute attacks span multiple medical subspecialties and may be precipitated by numerous medications, hormonal variations, calorie restrictions, and alcohol. AIP most commonly occurs in females with the age of onset between 15 and 40 years and rarely occurs before puberty.[103,104]

An acute neuropathy is found in approximately 40% of acute AIP attacks.[104-106] The neuropathy typically follows the onset of the attack by 1 to 4 weeks but may do so as late as 11 weeks. Although paresthesias and distal sensory changes may be a prodromal finding, the motor signs are much more prominent. Classically, the patient has symmetric upper extremity proximal weakness, but it may advance to involve the lower extremities. Generalized weakness is documented in approximately 42% of patients.[104] In AIP's most dramatic setting, the patient can have a rapid progression of weakness that leads to a flaccid involvement of all four extremities and respiratory compromise. When cranial nerves are involved, VII and X are the most frequently affected. Vascular compromise has been documented in individuals with vision loss, which may be monocular or total. Although this vision loss is usually transient, it can be permanent.[104]

AIP is often difficult to diagnose. The chief complaints are typically nonspecific abdominal and back pain. This colicky abdominal pain often leads to the consideration of surgical intervention. Notably, AIP is not associated with temperature elevation, leukocytosis, or rebound tenderness.[104,105] Neurologic and psychiatric symptoms often accompany the onset of attack. Of note, many antiepileptic medications can worsen or induce an attack. Worsening has been reported with phenytoin, carbamazepine, phenobarbital, valproate, lamotrigine, and potentially tiagabine and topiramate. Gabapentin and levetiracetam have been successfully used to alleviate symptoms. Oxcarbazepine is a consideration, but there are concerns regarding hyponatremia.[104,105]

Another important management issue in AIP is the significant hyponatremia and associated seizures that may be further precipitated by the use of intravenous fluids containing dextrose and water. Cardiovascular complications include hypertension and tachycardia. In its most extreme case, there may be significant hypertension with associated hypertensive encephalopathy and ischemic changes. An intravenous infusion of magnesium sulfate may be helpful.[104] Nutritional support is important in order to avoid a catabolic state, which will further complicate the clinical picture. In the event that nutrition is required intravenously, high-glucose solutions with

dextrose are recommended. Enteral feeding is preferred, with carbohydrates providing 50% to 60% of the energy needs.[104]

Diagnostically in AIP, urine and stool can be tested for alpha aminolevulinic acid (ALA). Also, there is a marked elevation of urinary porphobilinogen (PBG). In the blood, PBG deaminase is helpful in that its level is abnormal even between the acute attacks.[104] AIP should be a consideration in the differential diagnosis of progressive weakness. It is most often confused with GBS. The ascending weakness that is classic in GBS is rare in acute porphyria. Additionally, acute porphyria does not have elevation of the CSF protein or abnormalities of the cellular contents. The associated abdominal discomfort and tachycardia that are seen in porphyria would not be anticipated in GBS. Differential considerations should also include lead intoxication and hereditary tyrosinemia. Elder and Hift[104] provided a review of AIP therapy. The two recommended approaches are carbohydrate loading and administration of heme to replenish the depleted heme, which is the principal product of porphyrin metabolism. If the patient has severe symptoms such as seizures, hyponatremia, and initial signs of neuropathy, aggressive therapy should begin as early in the crisis as possible.[106] In mild attacks it may be possible to wait 24 hours to determine if the attack will resolve spontaneously. Carbohydrate loading is delivered as a 20% glucose solution provided via a central venous catheter. Studies that support the use of heme are primarily noncontrolled and have difficulty reaching statistical significance, but the overall consensus is that it does provide benefit. Daily measurements of urinary ALA or PBG may be a helpful clinical monitor.

Spinal Muscular Atrophy

Spinal muscular atrophy (SMA), a disease of the anterior horn cell, is most commonly inherited in an autosomal recessive manner. The responsible gene is the survivor motor neuron gene on chromosome 5q13.[107,108] SMA has three subtypes that present in childhood, and both autosomal dominant and X-linked inheritance have been reported. The combined incidence of all forms of SMA has been estimated as 1 case in 6000 to 25,700 live births.[109,110] After cystic fibrosis, SMA is the next most common fatal disease with an autosomal recessive pattern of inheritance.[109] The most severe form was previously known as Werdnig-Hoffmann disease but is now more commonly referred to as SMA type I. It classically presents shortly after birth. The findings should be apparent before age 6 months, and type I SMA is often clinically defined by the patient's inability to achieve independent sitting. SMA type II usually presents between ages 6 and 18 months and is characterized by the patient sitting but never standing or walking. In SMA type III, patients do stand independently and walk.

In patients with SMA type I, the examination reveals a floppy baby with proximal weakness greater than distal. The lower extremities are more affected than the upper extremities, and the only spontaneous movement in these infants may be in the hands and feet. When supine, the infant will assume a frog-legged position. Polyminimyoclonus, a fine tremor most easily visualized in the hands, may also be present in these patients. Areflexia, tongue fasciculations, facial weakness, and normal sensation are also found.[111,112] Retrospectively, some mothers will report decreased fetal movement during the pregnancy with the affected infant. Death often occurs before 2 years of age as a result of respiratory problems.[109] Patients with

clinical symptoms within the first day of life have a life expectancy between 2 and 6 months with a mean age at death slightly before 4 months.[113]

Patients with SMA type II usually have delayed motor milestones after having normal motor development in infancy. Polyminimyoclonus is also present in these patients. Life expectancy is variable, with many patients not surviving past adolescence.[109] Life expectancy can be enhanced, however, with fastidious respiratory care.[114] Not surprising was the correlation that patients with an earlier onset of the disease had an earlier death.[115]

In SMA type III, weakness is again more proximal than distal with the lower extremities being more severely affected. The gait exhibited in these patients has a waddling quality, and lumbar lordosis is also prominent.[116] If symptoms begin after age 2 years, ambulation may continue to a median age of 44 years.[116] If symptoms begin before age 2 years, ambulation continues to a median age of 12 years.[116] Life expectancy for patients with SMA type III may be the same as in the normal population because muscle weakness appears to stabilize in these patients.

Electrodiagnostic studies on these patients reveal normal motor conduction velocities. Over time, the amplitude of the compound muscle action potential may be decreased. Results from sensory nerve conduction studies are normal. EMG reveals evidence of acute denervation with spontaneous activity and chronic denervative changes with polyphasic motor units. Muscle biopsy specimens reveal angulated fibers suggestive of denervation. The creatine phosphokinase (CPK) level may or may not be increased. Genetic testing is utilized to confirm the diagnosis.

Respiratory complications are the most concerning aspect of this disease and include aspiration, pneumonia, and respiratory failure. Respiratory failure may even be the presenting symptom in SMA type I.[117] Respiratory muscle weakness results in restrictive lung disease with a weak cough and hypoventilation.[112] Hypercapnia is also a consequence of restrictive lung disease, and as a result supplemental oxygen may have devastating consequences including apnea and death.[112] If supplemental oxygen is needed, conventional ventilation or noninvasive ventilation should be instituted.

Other complications may also occur over time including scoliosis and contractures. Scoliosis also complicates pulmonary function over time because of chest wall alterations. In addition, feeding difficulties play a prominent role, particularly in the developing infant with SMA type I. If concerns arise, feeding evaluation should be performed to rule out aspiration. Supplemental feeding through nasogastric tube or gastrostomy may be necessary.[115]

Aggressive symptomatic treatment, including more frequent use of ventilation and gastrostomy, has been associated with longer life spans. Specific pharmacologic treatments have not been successful.[118]

Poliomyelitis

The paralytic form of polio represents only 1% to 2% of the actual infections. Aseptic meningitis represents less than 10% and is often thought to be a nonspecific illness; the remainder of those affected have no apparent infection. Patients with the paralytic disorder present with very high fevers, significant muscle pain, and lack of reflexes. Paralysis rapidly progresses over a few hours to a complete asymmetric loss of motor use in one or more extremities. Classically, the weakness peaks at 5 days.

The distribution of weakness is predominantly proximal and in the lower extremities, with cranial nerve abnormalities reported in 5% to 35% of the patients. Bowel and bladder problems may occur over the initial 3 days. Sensory abnormalities are rare. Classically, the “head drop” may occur on exam: As the examiner lifts the patient's shoulders and raises the trunk from supine, the head falls backward in a limp fashion. It is thought that this is not due to paralysis of the neck muscles because it can occur in the nonparalytic form. The clinical course may include significant respiratory muscle weakness. Involvement of the bulbar muscles, brain stem, and the respiratory center results in respiratory compromise. Cranial nerve involvement leads to paralysis of the pharynx and vocal cords and further poses difficulties in breathing. Respiratory compromise leads to most deaths in the paralytic form.[119] Typically, 50% of patients with any paralysis exhibit some degree of residual deficits, although most do improve. A 10% mortality is now reported in the patients with the paralytic form. Before mechanical ventilation, 60% of the individuals died.[119]

Early in the course of the pharyngeal infection throat cultures may reveal the poliovirus. Later in the course, the stool culture becomes increasingly helpful. Spinal fluid culture has lower sensitivity. Usually, the results of routine laboratory tests are unremarkable. Cerebral spinal fluid findings are characteristic of aseptic meningitis. In the first few hours after the onset of symptoms, polymorphonuclear leukocytes may predominate, but within 12 hours the predominance of lymphocytes is seen.[119]

Numerous other clinical manifestations may occur. In the viral myocarditis, the heart is extremely sensitive to development of arrhythmias. Hypertension is well recognized and can be severe enough to cause encephalopathy. Analgesics, including opiates, may be required for pain relief. Hot packs have been noted to be effective when applied every 2 to 4 hours. Constipation and bladder paralysis are major issues early in the course and should be monitored closely. The risk of aspiration and airway compromise necessitates a high level of vigilance. If the patient demonstrates respiratory compromise, a tracheostomy is indicated with accompanying mechanical ventilation.[119] Use of antiviral agents is debated. Additionally, some authors argue that steroids are not indicated in enteroviral infections.[119]

Children with mild weakness generally have full recovery. If paralysis is present, the recovery is ongoing for 2 years with 80% realized by 6 months.[119] Adults may have new symptoms long after the infection resolves, including weakness and muscle atrophy that are related to continued normal attrition of anterior horn cells.[120]

Polio-Like Syndromes

Polio-like syndromes have been reported, with West Nile virus and multiple subtypes of enterovirus (most notably D68) being prominent agents.[121-123] These cases are often associated with a prior illness (either gastrointestinal or respiratory) and may present with respiratory failure and an acute flaccid paralysis of one or more limbs consistent with anterior horn cell disease. Clusters of cases with acute flaccid myelitis have been described in California and Colorado (http://www.cdc.gov/ncird/downloads/acute-flaccid-myelitis.pdf). Encephalopathy and cranial nerve abnormalities are common, as is CSF pleocytosis. Some authors have suggested the use of interferon-α based on small case studies, but no blinded

and randomized studies have been published.[122-125] Prognosis may be more optimistic with some viruses. However, several series report poor motor recovery with enterovirus D68, likely due to significant motor neuron damage.[122,123]

Organophosphate and Carbamate Poisoning

The clinician must always maintain a high index of suspicion and consider poisoning in the differential diagnosis in patients with altered mental status, respiratory symptoms, or weakness (see also Chapters 127 and 128). Zweiner and Ginsburg[126] reported in their study of 37 children with organophosphate or carbamate poisonings that 43% of these patients were evaluated by their primary care doctor, and pesticide toxicity was not suspected. Patients commonly do not have a known history of exposure. Exposure to these substances may occur as inhalation, ingestion, or dermal contact. In one study of 37 infants and children with organophosphate and carbamate poisonings, 76% of these patients ingested these substances (which were improperly stored), 16% had transcutaneous exposure (through contact with treated carpets, linens, and lawns), and 8% were poisoned by an unknown etiology.[126] Cholinesterase, which is present in the neuromuscular junction, is irreversibly inhibited by organophosphates and reversibly inhibited by carbamate compounds. Therefore, a constellation of muscarinic, nicotinic, and central nervous system symptoms may occur.

Symptoms may originate from various systems. Muscarinic symptoms include miosis, excessive salivation, sweating, lacrimation, diarrhea, urination, and bradycardia. In severe poisonings, flaccid paralysis with areflexia is common. In moderate poisonings, muscle fasciculations may be present. Central nervous system symptoms include coma and seizures; however, seizures are less common in carbamate toxicity.[127] Pulmonary symptoms including bronchoconstriction, increased pulmonary secretions, and wheezing have been reported.[128] In one study of 52 children with organophosphate or carbamate poisoning, 100% of these patients exhibited hypotonia, stupor, or coma.[129] With further analysis of the 16 patients with organophosphate poisoning, the other common symptoms included miosis (56%), salivation (37%), pulmonary edema (37%), diarrhea (30%), and bradycardia (25%).[129] Various cardiac rhythms may occur with pathologic signs of cardiotoxicity.[130] Overall, carbamate poisonings are usually less severe and shorter in duration, although the symptoms are essentially the same as those found in organophosphate poisonings.[131]

If organophosphate and carbamate compounds are ingested, gastric lavage and activated charcoal should be initiated. If contaminated, the patient's skin and hair should be rinsed and cleansed thoroughly with soap, and clothes should be changed to reduce further exposure.[127]

In both forms of poisonings, atropine is used as an antidote for the muscarinic symptoms. Treatment with atropine, however, does not reverse the nicotinic symptoms, which include muscle weakness and respiratory failure. Atropine should be administered as quickly as possible and in adequate doses. In children older than 12 years, the dosing is 1 to 2 mg intravenously every 10 to 30 minutes. In children younger than 12 years, the initial dose is 0.05 mg/kg with maintenance doses of 0.02 to 0.05 mg/kg over 10 to 30 minutes.[128] In organophosphate and carbamate poisonings, the atropine dose is five to ten times greater than conventional atropine

dosing.[128] Atropine should be continued until the muscarinic symptoms begin to abate. The signs of atropinization include mydriasis, tachycardia, and xerostomia, and they help provide parameters for adequate dosing.[132] Atropine should be continued for at least 24 hours after severe exposures and then tapered if symptoms are improving.[128]

Pralidoxime chloride, the only cholinesterase reactivator in the United States, is an antidote for only the nicotinic symptoms of organophosphate poisonings; therefore atropine must be used concomitantly. Pralidoxime chloride does not help in carbamate exposures. Various doses have been reported for pralidoxime in patients older than 12 years. A conservative dose is 0.5 to 1 g IV over 15 to 30 minutes, repeated every 10 to 12 hours, beginning 1 to 2 hours after the initial dose. Another study suggests a 2-g loading dose with a continuous infusion of 1g/h for 48 hours. These doses have not been directly compared to each other. In patients younger than 12 years, the dose is 25 to 50 mg/kg IV over 15 to 30 minutes, repeated every 10 to 12 hours, beginning 1 to 2 hours after the initial dose.[128,133,134]

After the antidotes are given, the mainstay of treatment is supportive. If necessary, ventilation should be provided until the patient regains respiratory strength. Suctioning of secretions in both the oropharynx and in the respiratory tree is essential. Seizures should be treated with diazepam or lorazepam. Cardiac monitoring should be implemented because complex ventricular arrhythmias may occur.[130,135] Early feeding may prolong hospital stay.[136] Death usually occurs as a result of respiratory arrest and pulmonary complications, including excessive secretions, edema, and bronchoconstriction.[128]

Diagnosis is based on clinical findings and response to antidote medications. Serum and red blood cell cholinesterase levels should be obtained to assist in the diagnosis of organophosphate poisoning. Treatment should be initiated immediately and not delayed while waiting for cholinesterase level results. Cholinesterase levels do not assist in the diagnosis of carbamate exposure because the reversal of the enzyme occurs too rapidly to be quantified.

SECTION V

Renal, Fluids, Electrolytes

OUTLINE

CHAPTER 72

Renal Structure and Function

Maury N. Pinsk, Victoria F. Norwood

PEARLS

- The efferent blood supply from a single glomerulus will contribute to the capillary vascular supply of tubules from different nephrons. This arrangement of the vascular supply explains the patchy distribution of tubular damage after ischemic injury.
- Combinations of angiotensin-converting enzyme inhibitors and nonsteroidal antiinflammatory drugs inhibit afferent arteriolar vasodilation and efferent arteriolar vasoconstriction. In low flow states, these agents can cause a precipitous loss of glomerular filtration pressure and kidney function.
- Tubular dysfunction in the setting of acute kidney injury results in the inability to transport sodium into the medulla to establish concentration gradients, impairing the concentration of urine and resulting in diuresis. Furosemide and other loop diuretics, which also impair sodium transport into the medulla, are often ineffective at increasing urine output in this setting.

Renal Development

The human kidneys begin development in the third week of gestation, at which time they are primitive organs called pronephroi. These early kidneys are functional but regress as development unfolds. As gestation continues in the fourth week, the secondary kidney elements, the mesonephroi, form from parallel strips of mesoderm along the paravertebral axis. The mesonephroi begin functioning between the sixth and tenth week of gestation before involution in a cranial-caudal direction beginning at 10 weeks gestation. The definitive kidneys, or metanephroi, begin development at the fifth week of gestation and begin functioning between the tenth and fourteenth week. This kidney develops in the pelvis as the branching ureteric bud and undifferentiated metanephric mesenchyme interact in a complex series of reciprocal inductions.[1-3] These interactions lead to the formation of glomeruli, whereas vessels and tubules form from mesenchymal precursors, and distal tubules and collecting

ducts derive from ureteric bud epithelium. This process occurs in a centrifugal fashion so that deeper corticomedullary nephrons form earliest in organogenesis, whereas the more peripheral cortical nephrons form later. As the metanephros develops, the maturing kidney ascends into the retroperitoneal space to its final location with the upper poles at the T12 vertebra. During the ascent, the systemic blood supply is derived from more cranial aspects of the aorta and from the lumbar renal arteries at the final position of the kidney. The ureters elongate and canalize during the ascent to maintain drainage to the bladder. By the time human nephrogenesis is complete at 34 to 36 weeks of gestation, repeated cycles of mesenchymal induction, ureteric branching, and morphogenesis result in approximately 1 million nephrons per kidney.

Renal Anatomy

Normal human kidneys reside in the retroperitoneal space at the level of the T12 vertebra. The liver is superior to the right kidney and thus displaces it lower than the kidney on the left side. The spleen and stomach overlie the superior aspect of the left kidney. Kidneys, however, can be found in a variety of other locations and have altered morphologies as a result of alterations of the normal developmental program (reviewed by Schedl[4]). For example, failure of the kidney to ascend normally results in a pelvic kidney that has abnormal vascular supplies from the aorta and iliac vessels. Mesenchymal regions of the two kidneys coming in contact during early development likely cause fused kidneys, most commonly the horseshoe kidney. Partial or complete renal duplications comprise a variety of abnormalities that may arise from aberrant branching of the ureteric bud into the developing mesenchyme. Unilateral agenesis likely results from failure of ureteric bud development or abnormal mesenchymal induction, leading to regression of the metanephric mesenchyme and failed renal development.

Renal Vasculature

Vascular Development

Markers of early vascular development are expressed in undifferentiated metanephric mesenchyme, which suggests that the blood supply to the nephron develops at least partially from precursors inherent to the maturing kidney.[5] Migration of committed endothelial cells into the developing glomerulus occurs in response to secreted factors such as vascular endothelial growth factor, which is secreted under the transcriptional regulation of the oxygen-sensitive hypoxic inducible factor.[6] Control of the corresponding branching of extraglomerular vessels is an area of active study and may involve branching from existing vessels, de novo vessel formation, or both processes. These actions appear to be regulated in part by the renin-angiotensin system.[7]

Vascular Anatomy

The arterial supply of the kidney branches from the main renal artery and enters the kidney in a series of rays called interlobar arteries. The interlobar vessels branch at

the corticomedullary junction to run parallel to the surface of the kidney as arcuate arteries. Arcuate arteries penetrate the cortex as interlobular arteries, which ascend into the cortex in a radial pattern. It is from the interlobular arteries that afferent arterioles of the glomeruli arise. After filtration across the glomerular tuft, blood exits the glomerulus by efferent arterioles, which travel to the surface of the cortex and eventually feed the peritubular capillary vascular beds, the vasa rectae. The efferent arteriole of a single nephron can supply blood to multiple vasa rectae. The postglomerular vasculature of the cortex is supplied by efferent arterioles from midcortical and superficial cortical nephrons, whereas the blood supply to the medulla is entirely derived from juxtamedullary efferent arterioles. The vasa rectae of the medulla branch as they descend toward the papilla of the kidney and form the complex meshwork of the medullary capillary vascular beds. Only a few vessels of the vasa rectae eventually reach the papillary tip.

Venous drainage of the vasa rectae is divided into two types: the vessels of the deep medulla ascend to join the arcuate veins at the corticomedullary junction, and those of the superficial medulla ascend into the cortex to join the cortical capillary network and ultimately the interlobular and arcuate veins (Fig. 72.1). The arcuate veins join with the interlobar veins via the interlobular veins and finally drain into the main renal vein to join the main circulation.

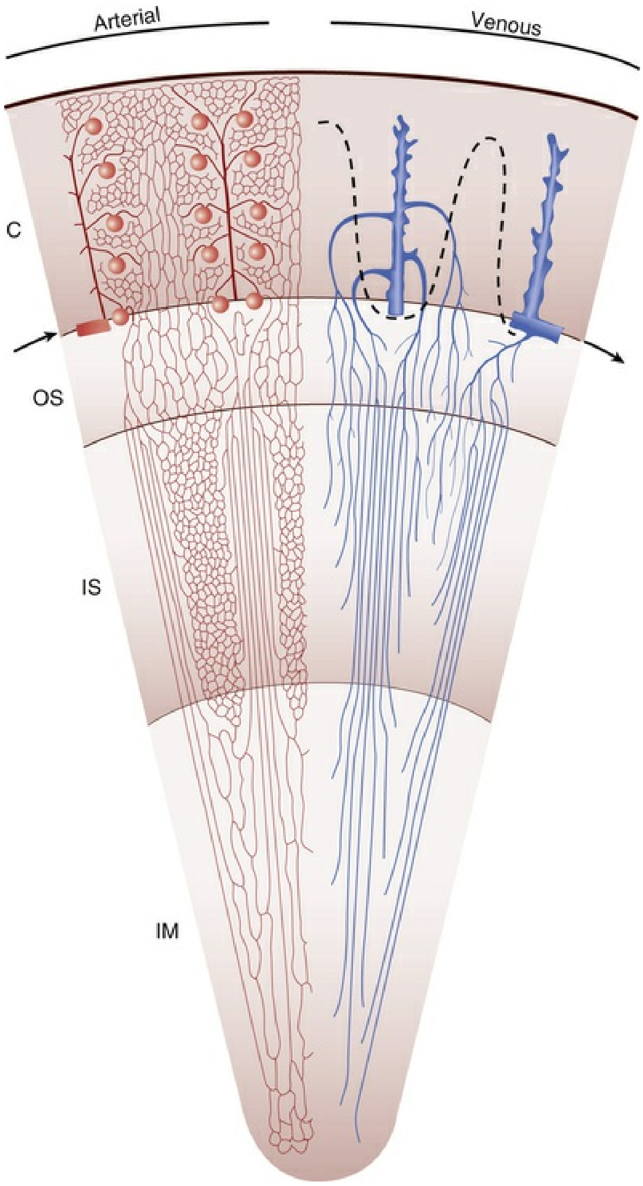

FIG. 72.1 The microvasculature of the mammalian kidney. Arterial supply *(left):* The arcuate artery *(arrow)* travels parallel to the surface of the kidney, branching into interlobular arteries that travel toward the kidney surface and further branching into afferent arterioles supplying each glomerulus. The efferent arterioles travel to the medulla forming the vasa rectae. Venous drainage *(right):* Interlobular veins receive blood from the vasa rectae of the medulla and superficial cortex. Interlobular veins drain into arcuate veins and ultimately rejoin the systemic circulation via the renal vein. *C,* cortex; *IM,* inner medulla; *IS,* inner stripe; *OS,* outer stripe. Pediatr Nephrol. 2014;29:659-664.)

Vascular Function

The kidneys are extraordinarily vascular organs; they receive 15% to 18% of cardiac output in the neonate and up to 20% of cardiac output in the adult.[8] Blood flow to

the kidney is tightly regulated to ensure continued renal function over a range of blood pressures. Sympathetic α_1-receptors, myogenic contraction, and vasoactive mediators control vascular resistance and provide autoregulation of renal blood flow. Maintenance of glomerular filtration rate at the level of the glomerulus occurs by vasoconstriction of efferent arterioles in response to vasopressors such as angiotensin II, whereas afferent arterioles relax in response to vasodilators such as prostacyclin. Circulating angiotensin II is elevated in the neonate,[9] as are corresponding vasodilators.[10,11] Therefore infants have a decreased capacity to regulate renal blood flow, which explains their increased susceptibility to renal ischemia in hypotensive states.

Nephron Unit

The nephron unit consists of a glomerular tuft, proximal tubule, loop of Henle, distal tubule, and collecting duct (Fig. 72.2). The proximal tubule is an extension of the urinary space of the glomerulus and courses into the loop of Henle. Two types of nephrons are characterized on the basis of the location of the glomerulus and the path of the loop of Henle: the juxtamedullary nephrons and the cortical nephrons. Most nephrons are cortical in location, have short loops of Henle that extend into the superficial medulla, and have a relatively low capacity to reabsorb solute and water. Juxtamedullary nephrons are fewer in number but have longer loops of Henle that extend deep into the medulla. Consequently, these nephrons absorb larger amounts of salt and water, generate steep osmotic gradients, and produce highly concentrated urine. Regardless of the location of the nephron, the loop of Henle returns to the cortex to become a distal tubule. The distal tubule then continues on to form the collecting duct, the final common pathway for several nephrons draining into the renal papilla.

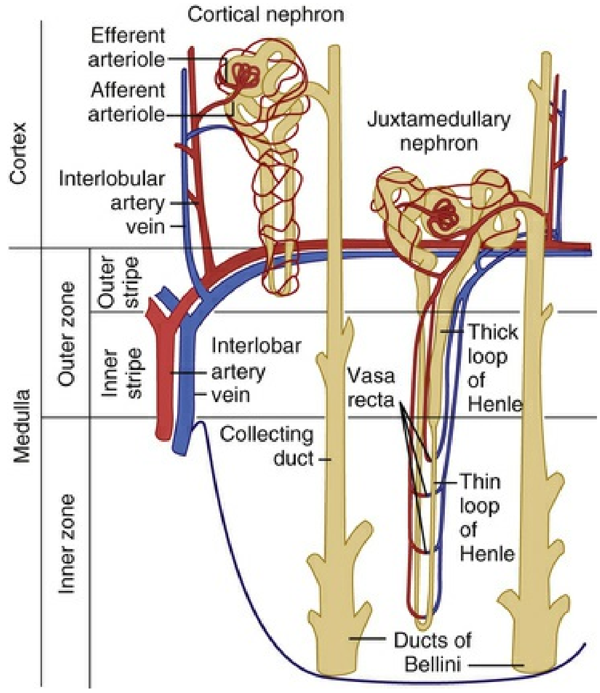

FIG. 72.2 The nephron structure. (From Guyton A. Formation of urine by the kidney: I. Renal blood flow, glomerular filtration, and their control. In: Wonsiewicz M, ed. Textbook of Medical Physiology. ed 8. Philadelphia: WB Saunders; 1991.)

Nephron Development

Nephron development occurs through a complex, interactive series of processes.[1-3] Nephron development begins with the out-pouching of ureteric epithelium, the ureteric bud. This precursor to the collecting duct encroaches on undifferentiated mesenchyme in the caudal retroperitoneal space and induces the development of an epithelial cell condensate, the precursor to the glomerulus and tubule (Fig. 72.3). Simultaneously, factors within the metanephric mesenchyme induce the ureteric bud to continue branching. The epithelial condensate forms a vesicle that convolutes progressively into a comma-shaped body and then an S-shaped body, signifying the development of the urinary space and early tubule segments. The terminal portion of the tubule is contributed by the ureteric bud derivatives and forms the collecting duct. The mechanisms by which the ureteric bud epithelial derivatives link to the corresponding mesenchymal derivatives in the distal nephron remain unknown but may involve mesenchymal to epithelial cell transitioning (reviewed in Naylor). The glomerular capillary loops form through the angiogenic processes of committed endothelial cells,[5] and supporting mesangial cells develop from committed metanephric mesenchyme with myoblastic characteristics.[12] Nephrogenesis in the human is essentially complete by the thirty-fourth week of gestation, but functional maturation continues into the second year of life.[1-3]

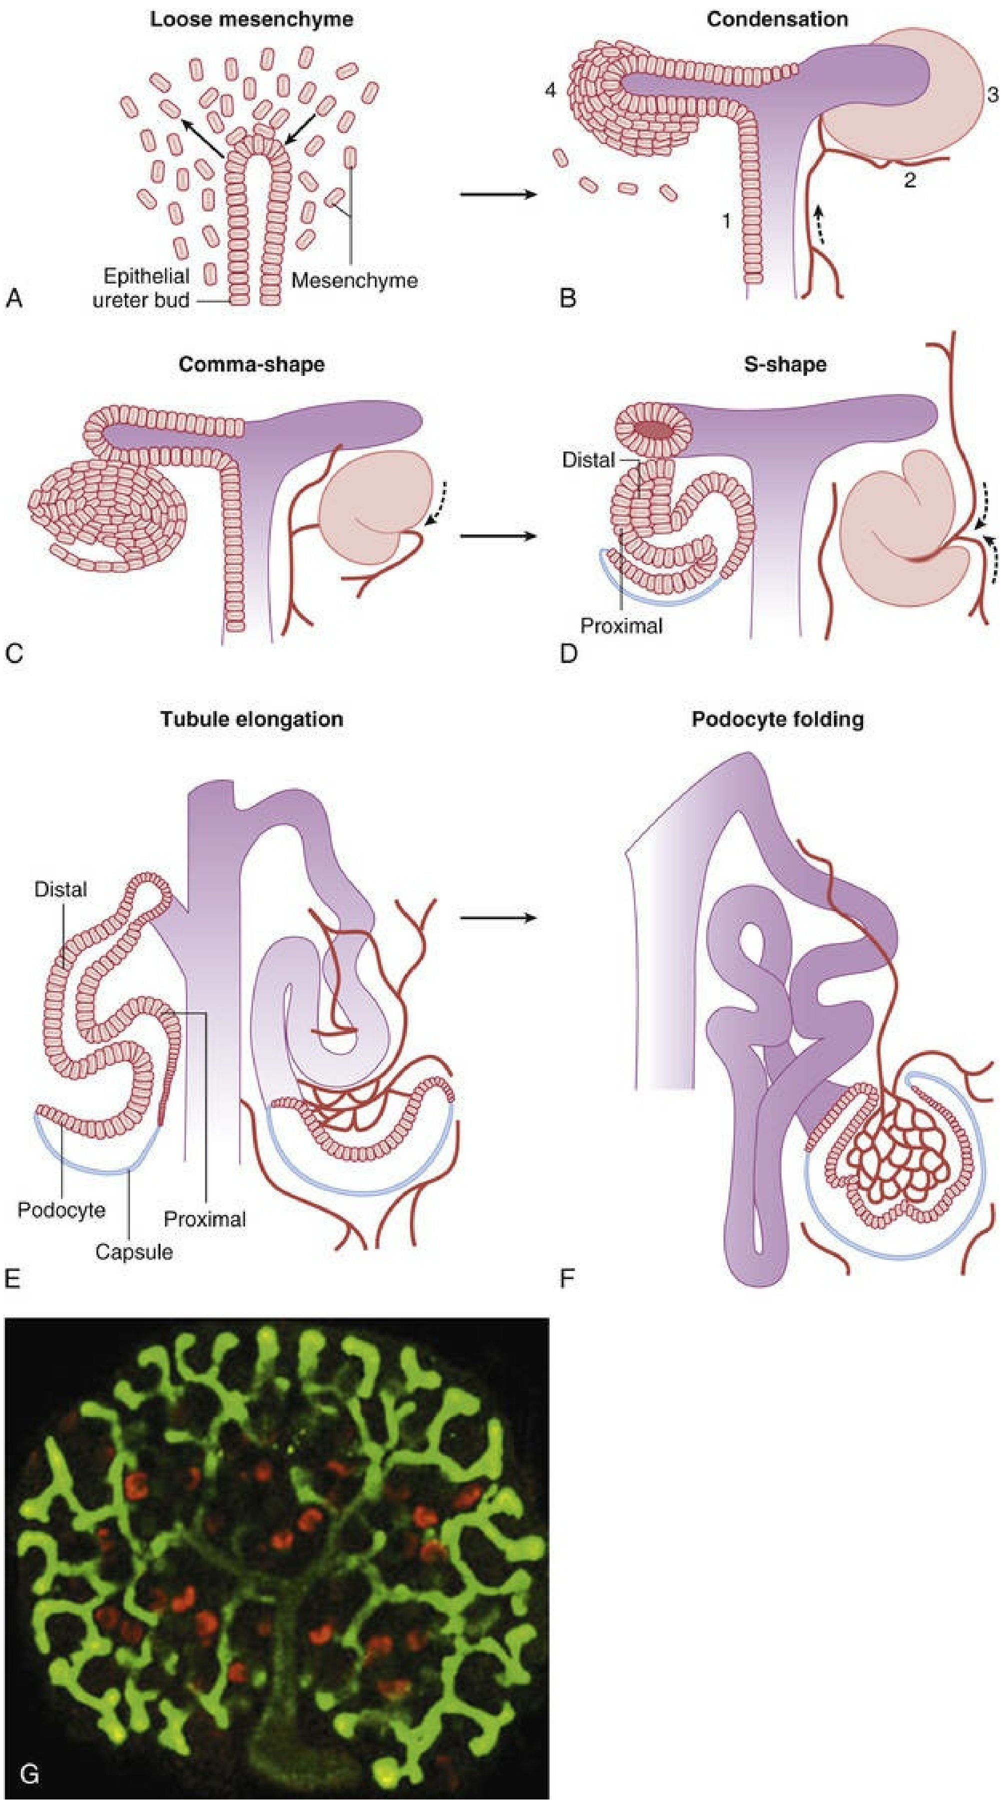

FIG. 72.3 Branching morphogenesis of the developing kidney. (A and B)

The ureteric epithelium interacts with the metanephric mesenchyme, inducing condensation of the mesenchyme (*1* = ureteric epithelium, *2* = vasculature, *3* = undifferentiated mesenchyme, *4* = condensed mesenchyme [precursor to epithelium]). (C and D) Infolding of the glomerular epithelium forms a comma-shaped body, followed by development of an S-shaped body. (E and F) Infolding of the glomerular epithelium and vascular structures and elongation of the tubular elements form the completed nephron. The mature glomerular capillary network is likely initiated during C and D. (G) Fluorescent microscopy of branching morphogenesis in organ culture. (A to F, From Gomez RA, Norwood VF. Recent advances in renal development. Curr Opin Pediatr. 1999;11:136. G, Courtesy John Bertram, Kidney Development and Research Group.)

Glomerular Anatomy

The glomerular tuft consists of endothelial cells, specialized epithelial cells (podocytes), and supporting mesangial cells. Epithelial cells also form the urinary compartment into which ultrafiltrate passes (Bowman space). Endothelial cells and podocytes sit on opposite sides of the glomerular basement membrane, the entirety of which forms the filtration apparatus. The epithelial side is characterized by fingerlike extensions of the podocyte cell membrane that interdigitate to form a mesh on the glomerular basement membrane. Glomerular endothelial cells on the blood side of the filtration barrier are highly fenestrated, thereby enhancing solute and fluid transfer. Mesangial cells form the supporting network of the glomerular structure, provide some phagocytic function, and participate in control of glomerular filtration.

Glomerular Function

Filtration is the primary function of the glomerulus. For filtration to occur, there must be a gradient across the glomerular basement membrane favoring the movement of filtrate to a low-pressure area. There are generally four factors that determine the quantity of filtrate obtained across the glomerular basement membrane (Fig. 72.4). First, hydrostatic pressure in the glomerular capillary drives filtration of fluid across the glomerular basement membrane. If the blood flow to the glomerulus decreases, the hydrostatic pressure also drops, which necessitates an increase in efferent vascular resistance to maintain glomerular perfusion pressure. Angiotensin II, prostaglandins, and renal sympathetic activity control afferent and efferent vascular tone to carefully regulate glomerular vascular resistance.

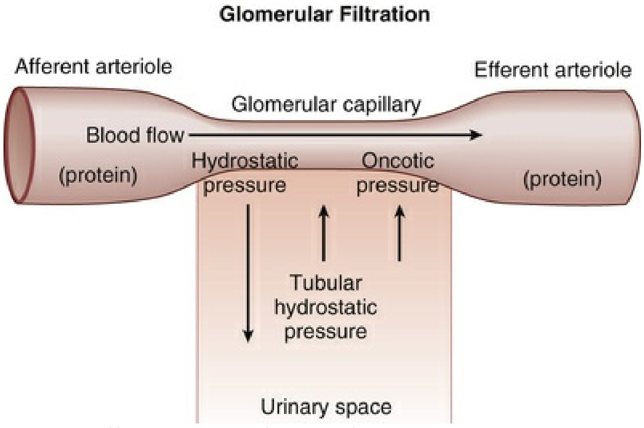

FIG. 72.4 Forces affecting ultrafiltrate formation in the isolated nephron.

The second factor controlling filtration is the oncotic pressure of the blood entering the glomerulus. As blood is filtered and water leaves the vascular compartment, the oncotic pressure in the blood compartment rises, retarding the further passage of fluid across the glomerular basement membrane. In situations of low oncotic pressure, such as nephrotic syndrome, the initial rate of ultrafiltrate formation is increased because of low oncotic pressure. Low oncotic pressure can also cause a redistribution of intravascular volume into peripheral tissue spaces, resulting in decreased vascular hydrostatic pressure and forcing ultrafiltrate production to drop.

The third factor determining the efficiency of ultrafiltrate formation is tubular hydrostatic pressure, or the resistance within the urinary space. In urinary tract obstruction, tubular hydrostatic pressure limits ultrafiltrate generation as it rises above the hydrostatic pressure of the blood compartment and arrests ultrafiltrate generation.

The last important factor in the determination of ultrafiltrate formation is the available glomerular basement membrane available surface area and the filtration efficiency. Physiologically, the functional size of the glomerular basement membrane can be determined at the whole kidney level or at the glomerular level. At the whole kidney level, the number of nephrons receiving adequate blood supply determines glomerular basement membrane area available for filtration. For example, shunting of blood from the cortex into the medulla, as seen in hepatorenal syndrome, effectively decreases the available glomerular basement membrane area by reducing the number of actively filtering nephrons. At the glomerular level, glomerular basement membrane area can be altered by mesangial cell function. In hypovolemic states, mesangial cell contraction is thought to decrease glomerular basement membrane area in response to hormonal mediators, resulting in decreased filtration and preservation of intravascular volume.[13] The efficiency of basement membrane filtration is also affected by disease states including immune complex deposition, fibrosis, or complement activation, which disrupt the integrity and efficiency of the membrane. Finally, selectivity of the filtration barrier is determined by the ability of the basement membrane to permit some materials to pass into the urinary space while restricting others to stay in the blood compartment. Selectivity appears to be the result of both size discrimination of the glomerular basement membrane and the orientation of podocyte foot processes on the glomerular basement membrane. Disruption of the normal podocyte physiology results in nephrotic range proteinuria.[14,15]

Tubular Anatomy

Proximal Tubule

The proximal tubule consists of polarized epithelia with a distinctive apical brush border not seen in other parts of the tubule (Fig. 72.5). The brush border increases the surface area of the luminal side of the cell so that maximal contact with the ultrafiltrate is made. Increased surface area facilitates reabsorption of solute and water, which occurs through an abundant variety of sodium-coupled transport proteins. Also on the brush border membrane are ion channels and ion exchange proteins that maintain electrochemical gradients across the apical membrane. On the basolateral aspect of the proximal tubular cells are located sodium-potassium adenosine triphosphatase (Na/K-ATPase) proteins and a high density of mitochondria. It is through the Na/K-ATPase that favorable sodium and electrochemical gradients are generated to facilitate transcellular and paracellular transport of solutes and water. The lateral membranes of the proximal tubule cells are characterized by the presence of cell-cell adhesion complexes called tight junctions. Tight junctions maintain the polarity of the proximal tubule cells by separating transport proteins on the apical side from the gradient-generating basolateral membrane proteins.

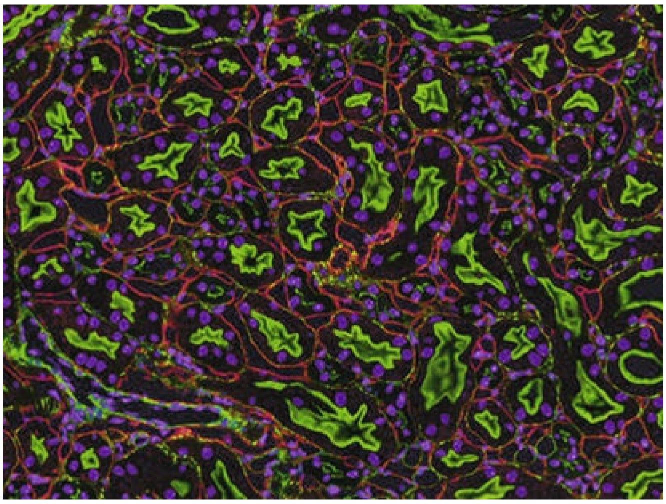

FIG. 72.5 Proximal and distal tubules. (Courtesy Thomas J. Deerinck, National Center for Microscopy & Imaging Research.)

Loop of Henle

The cortical and juxtamedullary nephrons are defined by their position within the cortex but also by the length of the loop of Henle. The juxtamedullary nephrons have loops of Henle that extend deep into the hyperosmolar medulla, whereas most nephrons are cortical and have loops that reach only the mildly hyperosmolar outer medulla. The properties of the epithelial cells change throughout the length of the loop of Henle. The proximal portions have cells with prominent microvilli and permeable cell junctions that permit passage of fluid via aquaporin-1 channels.[16] The distal sections of the loop of Henle consist of flat epithelia lacking microvilli and are

devoid of aquaporin-1 channels; the thin ascending limb of the loop of Henle is impermeable to water and urea but transports other solutes, particularly chloride, and is important in assisting with the establishment of medullary gradients.[17]

An abrupt transition occurs at the beginning of the thick ascending limb of the loop of Henle (TALH). The TALH is impermeable to water but transports solute in an active, ATP-dependent manner. These cells do not have prominent microvilli but do have dense tight junctions. These tight junctions allow solute, but not water, to move among cells into the basolateral space. TALH cells have dense localization of mitochondria and Na/K-ATPase at the basolateral membrane that generate gradients for solute transport across the luminal surface. Compared with the proximal tubule, the TALH basolateral surface is larger than the luminal surface and accommodates a larger number of Na/K-ATPase pumps.[18] At the distal end of the TALH, the tubule courses back toward its originating glomerulus. Here a small plaque of tall, narrow cells, the macula densa, contacts the vascular pole and extraglomerular mesangial cells (Fig. 72.6). The primary function of the macula densa cells appears to be the detection of tubular chloride content and the regulation of glomerular filtration.

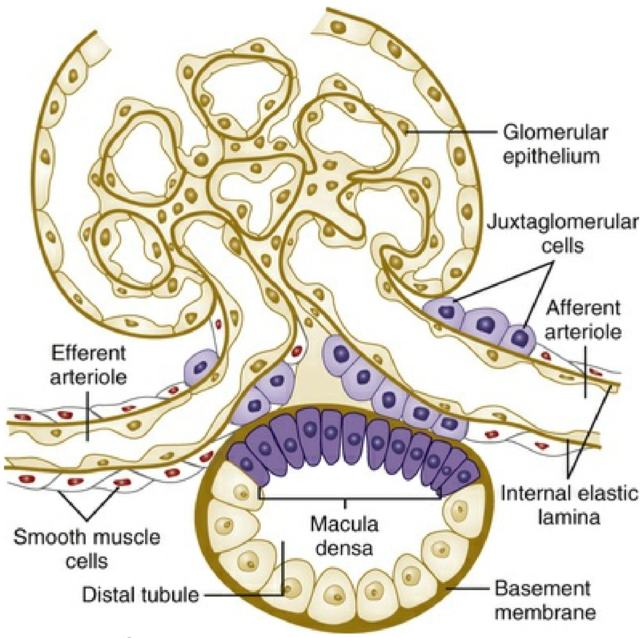

FIG. 72.6 Structure of the juxtaglomerular apparatus. (From Guyton A. Formation of urine by the kidney: I. Renal blood flow, glomerular filtration, and their control. In: Wonsiewicz M, ed. Textbook of Medical Physiology. ed 8. Philadelphia: WB Saunders; 1991.)

Distal Nephron

The distal nephron segment from the TALH to the beginning of the collecting duct has three distinct morphologic regions. The first region is the distal convoluted tubule, the cells of which contain the luminal sodium chloride transporter (NCC2, or thiazide-sensitive transporter) and the highest density of mitochondria in the nephron. The basolateral membrane of this segment is composed of interdigitating membranes from adjacent cells, giving the appearance of membranous convolutions. This composition maximizes the basolateral surface area to accommodate the high

density of mitochondria and allow for high levels of Na/K-ATPase function. Moving distally, the tubule contains transitional cells that have a smaller basolateral surface area and fewer mitochondria at the basolateral membrane. Transitional cells express both the NCC2 channel and the luminal epithelial sodium channel (ENaC), with the quantities of ENaC increasing and NCC2 decreasing with distal progression along the segment.

The next segment is the connecting tubule, where cells show even fewer mitochondria and smaller basolateral membranes. These cells are distinguished by a more flattened appearance, an expression of ENaC, and a luminal potassium channel (ROMK), but not NCC2. The basolateral membrane is expanded to some degree by infoldings of the basal membrane, but there is no interdigitation from neighboring cells. Because of the presence of magnesium transporters (TRPM6) and calcium transporters (TRPV6), there is also a role for divalent cation regulation.[19,20]

The last segment in the distal nephron is the collecting duct. The primary cells of this segment, the principal cells, have apical vacuoles, some of which store aquaporin-2 channels. They also contain mineralocorticoid receptors and apical sodium channels that function in sodium and potassium balance. The basolateral membrane is infolded but to a lesser degree than other cells in the region. These folds diminish in cells of the medullary collecting duct compared with those in the cortical collecting duct. In the medullary portions of the collecting duct, urea transporters again appear.

Two forms of intercalated cells, "type A" and "non–type A," exist as single cells interspersed throughout the distal nephron. These cells have prominent microfolds in the apical membrane, have high densities of mitochondria, and express several important membrane proteins such as the luminal H^+-ATPase and H^+/K^+-ATPase, as well as cytoplasmic carbonic anhydrase, serving an integral role in acid-base balance. The essential difference between type A and non–type A intercalated cells is that cell polarity is opposite in the two cell types. In "type A" intercalated cells, the apical membrane contains an H^+/K^+-ATPase, whereas the basolateral membrane contains AE1, a bicarbonate/chloride exchanger that provides a mechanism for proton secretion. The non–type A intercalated cell has vacuolar H+-ATPase on the basolateral and apical surfaces and a chloride bicarbonate exchanger, pendrin, on the apical surface, allowing for both bicarbonate secretion and proton reabsorption.[21] Generally, the number of type A and non–type A intercalated cells can vary to accommodate the acid-base status in the blood.[22]

Tubular Function

Although the function of the glomerulus is filtration, the function of the tubule is to modify the ultrafiltrate to maintain metabolic balance.

Proximal Tubule

Solute and water are transported in the proximal tubule via both paracellular and transcellular routes (Fig. 72.7). Paracellular transport is a high-flux means of moving water and solute between cells along chemical or electrical gradients generated by the basolateral Na/K-ATPase. The mechanism for high flux movement of sodium out of the lumen is explained by a net luminal positive charge generated by the basolateral Na/K-ATPase and net anion reabsorption. The bulk of the sodium

therefore follows an electrochemical gradient through paracellular pathways into the blood space. The same principle applies to other cations, such as calcium, which are reabsorbed down electrochemical gradients in the proximal tubule. Neutrally charged solutes move between cells following concentration gradients, the transport becoming less effective more distally as the gradient dissipates. Water movement generally follows sodium movement and is facilitated by the high oncotic pressure of the peritubular capillary network. This favorable osmotic gradient allows for reabsorption of approximately 70% of the filtered water in the adult proximal tubule.

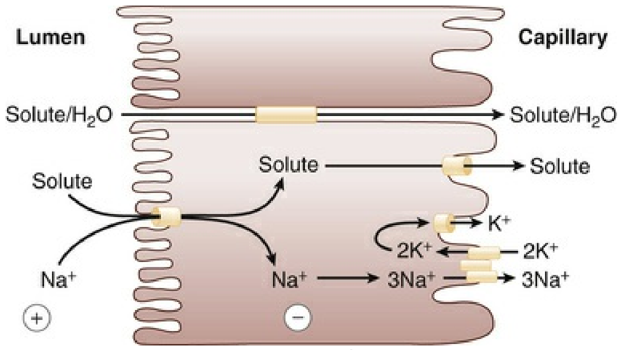

FIG. 72.7 Proximal tubule transport of solute and water. Apical solute reabsorption (glucose, amino acids, phosphate, and organic acids) is sodium coupled and follows an electrochemical gradient generated by basolateral sodium-potassium adenosine triphosphatase (Na/K-ATPase) activity.

Transcellular movement of solute is a high-resistance method of sodium-coupled transport that results from electrochemical and concentration gradients established by the basolateral Na/K-ATPase (see Fig. 72.7). The Na/K-ATPase pumps three sodium molecules into the basolateral extracellular milieu against a concentration gradient and imports two potassium molecules into the cell against a concentration gradient. The process, which is ATP dependent, establishes a low intracellular sodium concentration and permits luminal sodium entry along a concentration gradient coupled with solutes such as phosphate, glucose, amino acids, and organic acids. In a similar fashion, protons are exported from the luminal membrane by a Na/H+ exchanger that exploits the intracellular movement of sodium to facilitate the export of protons. Bicarbonate is indirectly absorbed through the activity of luminal carbonic anhydrase and the Na/H+ exchanger. The high oncotic pressure of the blood in the arterioles and early vasa recta drives transcellular water reabsorption in the proximal tubular cells via constitutively expressed aquaporin-1 channels that permit water to flow from lumen to vasculature.[23] Some proximal solute reabsorption is modifiable by hormone activity. Parathyroid hormone binding to the proximal tubule receptors activates several second messenger systems that ultimately result in decreased sodium-phosphate transporter activity and phosphate excretion.[24] The proximal tubule is also a site of hormone production, with 1α-hydroxylase activity converting 25-hydroxyvitamin D to the active 1,25-dihydroxy form. This conversion permits vitamin D to act in calcium and phosphate metabolism.[24]

Maturational development of the proximal tubule imparts functional differences

in neonatal proximal tubules compared with those in adult kidneys. The relatively low outer cortical nephron blood flow in infancy results in a generalized decrease in proximal tubule resorptive capacity because fewer nephrons participate in active solute and water reabsorption. In the neonate, the proximal tubule also expresses specific neonatal isoforms of the Na/H+ exchanger, has decreased chloride permeability, and expresses different permeability proteins (claudins) in the transcellular space. As a result, neonatal reabsorptive capacity is reduced compared with adults.[25] In addition, hormone receptors are expressed in fewer numbers or may have higher thresholds for activation in the neonate. For example, isoforms of sodium-phosphate transporters of the premature neonate exhibit a relatively low sensitivity to parathyroid hormone but a high transport capacity for phosphate, resulting in lower urinary excretion of phosphate and higher serum phosphate levels than those seen in adults.[26]

Loop of Henle

The loop of Henle plays an important role in establishing the osmotic gradients facilitating water reabsorption in the kidney. In the descending limb of the loop of Henle, the tubular epithelium is impermeable to solute but not water. Therefore as ultrafiltrate passes down the descending loop of Henle, ultrafiltrate becomes increasingly hyperosmolar as water leaves the luminal space. Water permeability decreases, however, in the ascending loop, and solute transporters become more prevalent, allowing the filtrate to become hypoosmolar by the time it reaches the outer cortex.

The thick ascending loop of Henle is responsible for roughly 25% of the total sodium reclamation in the kidney, primarily by the NKCC2 channel, that allows one sodium, one potassium, and two chloride ions to move from the tubular lumen into the cell.[27] Potassium subsequently leaks back into the lumen via the ROMK potassium channel, causing the lumen to become positively charged. This electrochemical gradient permits paracellular reabsorption of cations such as calcium and magnesium as they are propelled out of the tubular lumen.

The reabsorption of sodium in the TALH also helps establish osmotic gradients in the renal interstitium by the countercurrent amplification mechanism (Fig. 72.8). Although sodium, potassium, and chloride are absorbed into the interstitium, back leak of ions occurs into the descending limb of the loop of Henle, thereby increasing the concentration of solute in the descending limb tubular fluid. As this fluid passes into the ascending loop of Henle, the higher sodium content is also reabsorbed into the interstitium, augmenting the osmotic gradient in the medulla. Under normal conditions, ultrafiltrate leaving the ascending loop of Henle is more dilute than that entering the descending loop because of the proficient solute reabsorption in the late ascending limb. Loop diuretics such as bumetanide or furosemide block the NKCC2 channel function and impair the ability both to establish osmotic gradients and to reabsorb solute. The result is the production of large volumes of urine that is isotonic to plasma. In the immature kidney, the loop of Henle is relatively short and impedes the ability to set up steep osmotic gradients. In the setting of stable vasopressin levels, neonatal urinary concentrating ability is relatively weak compared with that of the mature adult kidney.[28]

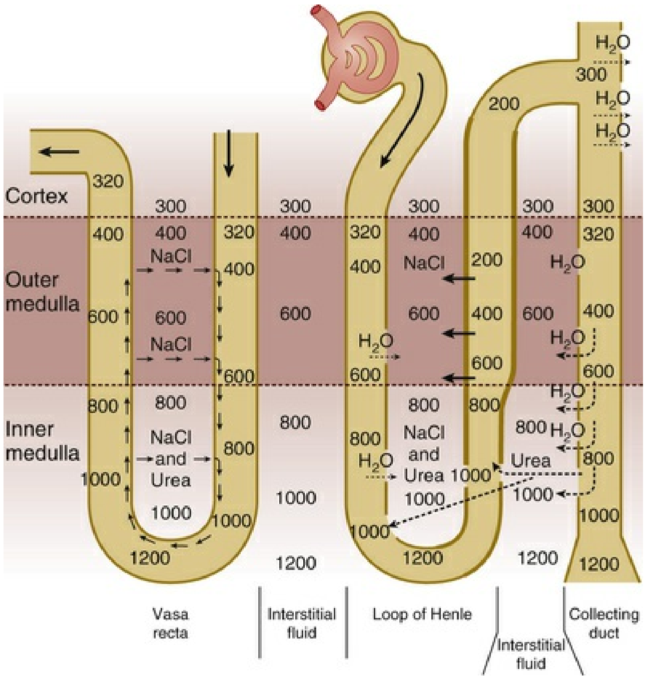

FIG. 72.8 The countercurrent amplification mechanism permitting urinary concentration. (From Guyton A. Renal and associated mechanisms for controlling extracellular fluid osmolality and sodium. In: Wonsiewicz M, ed. Textbook of Medical Physiology. ed 8. Philadelphia: WB Saunders; 1991.)

The thick ascending loop of Henle returns to its glomerulus of origin where the tubular epithelium is attached to the triangle between the efferent and afferent arteriole. The tubular epithelium in contact with the glomerulus contains about 15 to 20 cells in the form of a plaque, called the macula densa (see Fig. 72.6). The macula densa actively reabsorbs sodium, potassium, and chloride through the NKCC2 channel and, in doing so, acts as a sensor of tubular chloride concentration.[29] This sensing mechanism is integral to the functioning of the juxtaglomerular apparatus, which consists of the macula densa, the afferent arteriole containing renin-producing granular cells, the efferent arteriole, and the extraglomerular mesangium. In response to low tubular chloride, such as in hypovolemia, the macula densa secretes chemical mediators (prostaglandins, nitric oxide, adenosine, and ATP) that trigger renin release from the granular cells in the afferent arteriole.[30] Similar effects can be induced by sympathetic nervous system stimulation and arteriolar baroreceptor activation.[31]

Renin activity ultimately leads to the production of the potent vasoconstrictor angiotensin II, vascular smooth muscle contraction in the efferent arteriole, increased efferent arteriolar vascular resistance, and a rise in glomerular perfusion pressure.[31] The macula densa also signals the mesangial cells and neighboring smooth muscle cells to contract through a process that involves gap junction signaling and calcium flux. This contraction results in increased vascular tone and decreased effective filtration area of the glomerular basement membrane.[32,33]

Distal Tubule

The distal convoluted tubule is also a site of active sodium reabsorption and helps fine-tune the urinary filtrate. When tubular fluid enters the distal convoluted tubule, it is relatively dilute because of active solute reabsorption in the TALH. Thus

reabsorption of sodium and chloride in this segment occurs against a concentration gradient. Sodium and chloride are actively reabsorbed through the luminal thiazide-sensitive cotransporter (NCCT) following electrochemical gradients generated by the basolateral Na/K-ATPase. However, regulation of the NCCT, and hence sodium flux, is modifiable through a series of modulator kinases (WNK-1 and WNK-4).[34] Approximately 10% of filtered calcium is also reabsorbed from the luminal space in the distal convoluted tubule through parathyroid hormone activation of ATP-dependent TRPV5 calcium channels.[35] Once inside the cell, calcium is sequestered by calbindin-D28k, a protein that facilitates the transport of calcium to the basolateral membrane. Calcium exits the cell through either a basolateral Na-Ca exchanger, NCX1, or the plasma membrane Ca efflux ATPase.[35]

Collecting Duct

The collecting duct also fine-tunes the final composition of the renal ultrafiltrate adjusting sodium, potassium, water content, and acid-base balance. Approximately 5% of the filtered sodium is reabsorbed at this location and occurs through active transport. Sodium enters the cell through apical epithelial sodium channels (ENaCs) and generates a luminal electronegative gradient.[36] Consequently, the excretion of cations such as potassium (principal cell) or protons (a-type intercalated cell) is favored (Fig. 72.9). Because relatively little potassium is in the tubular fluid when it reaches this segment, potassium excretion down a concentration gradient is facilitated. As potassium is excreted, urine flow keeps the concentration in the tubular fluid low, and the favorable gradient is maintained. In states of low urine flow the tubular potassium concentration rises, the gradient is reduced, and potassium excretion decreases.

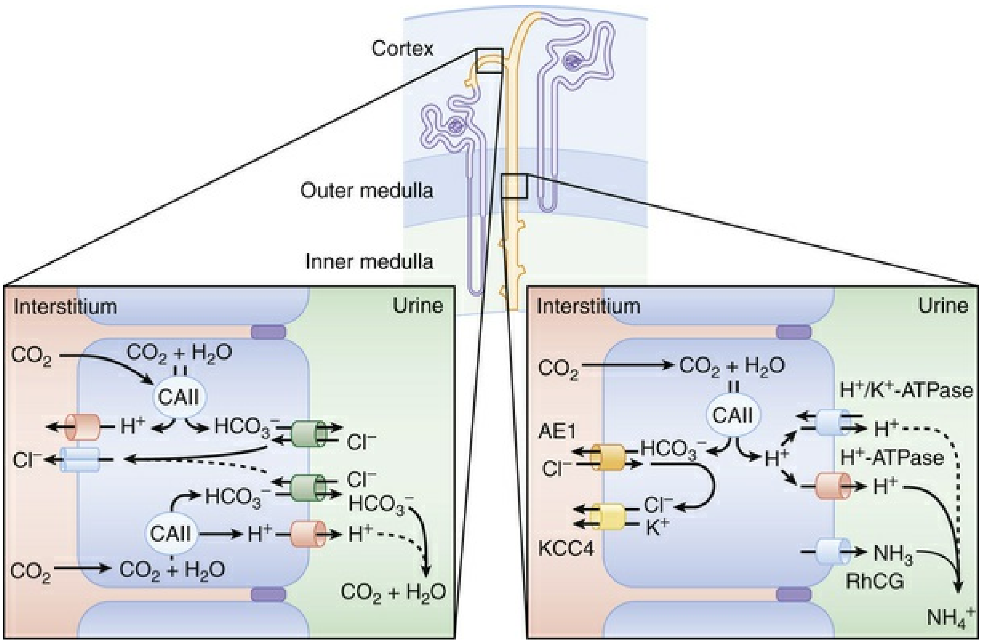

FIG. 72.9 Two types of intercalated cells. Intercalated cells are expressed from the late distal convoluted tubule to the initial third of the inner medullary collecting duct *(shaded red). Left,* Cell model of non–type A intercalated cell. These cells express on the luminal membrane the

chloride/bicarbonate exchanger pendrin mediating bicarbonate excretion and chloride absorption. Bicarbonate is produced from CO_2 and H_2O catalyzed by carbonic anhydrase II (CAII). Non–type A intercalated cells express also V-type H^+-adenosine triphosphatases (ATPases), which can be found on the basolateral or luminal membrane and may drive pendrin transport activity. Chloride is released across the basolateral membrane through chloride channels that consist of ClC-kb and Barttin subunits. *Right,* Cell model of type a intercalated cell. Bicarbonate and proton generation is catalyzed by CAII, providing protons for luminal V-type H^+-ATPases and bicarbonate for basolateral chloride/bicarbonate exchangers, including AE1. Type A intercalated cells also express basolateral KCC4 KCl-cotransporters, which may function in maintaining in low intracellular chloride. Type A intercalated cells also express on their luminal membrane H^+/K^+-ATPases that are not further discussed in this review and serve mostly for preservation of potassium during potassium deficiency. Moreover, both type A and non–type A intercalated cells participate in ammonium excretion. (Adapted from Wagner CA, Devuyst O, Bourgeois S, et al. Regulated acid-base transport in the collecting duct. Pflugers Arch. 2009;458:137-156.)

Potassium excretion and sodium reabsorption are also enhanced by the presence of aldosterone. Binding of aldosterone to its receptor and subsequent translocation to the cell nucleus induces transcription of the luminal sodium channel and basolateral Na/K-ATPase.[37] Increased efficiency and numbers of ENaCs on the luminal membrane tend to increase cell permeability to sodium, and this increase allows the tubular fluid to become more negatively charged after the influx of sodium. This process is facilitated by the increased activity and number of Na/K-ATPase pumps at the basolateral membrane, which creates larger electrical gradients. The net result is an increased capacity to excrete potassium or, in the hypokalemic state, an increased capacity to excrete protons.

The electrical gradient in the collecting duct also favors proton secretion into the tubular lumen, but the chemical gradient does not; the pH in the lumen can be as low as 5, whereas that of the intracellular space is 7.3. Excretion of protons occurs through an apical H-ATPase in the a-type intercalated cells and is also increased by aldosterone action in principal cells, as previously described. Protons secreted into the lumen are bound by ammonia (NH_3) to form NH_4^+ or are bound by other titratable acids such as phosphate or sulfate. This sequestration lowers the concentration of free protons in the ultrafiltrate, prevents diffusion of protons back into the intracellular space, and ultimately promotes acid secretion.

The collecting duct is also responsible for establishing the final concentration of the urine by controlling water reabsorption. At the beginning of the medullary collecting duct, the ultrafiltrate remains relatively dilute and the cells are relatively impermeable to water and solute (see Fig. 72.8). In the setting of hypovolemia or hyperosmolarity, arginine vasopressin binds to V2 vasopressin receptors on the basolateral membrane of the medullary collecting duct cell. V2 receptor signaling results in aquaporin-2 channel migration from intracellular vesicles to the apical surface, and this migration increases tubular permeability to water. Because of the high interstitial osmolality, water is reabsorbed through the aquaporin channels along an osmotic gradient into the blood space causing increased urinary concentration.[38]

Although largely established by active sodium reabsorption in the TALH, the

medullary osmotic gradient is also maintained by the presence of urea gradients generated in the collecting tubule (see Fig. 72.8). As tubular fluid moves down the collecting duct, the water entering the interstitium allows the urine to become more concentrated and the urea concentration to rise. The interstitium, however, becomes less hyperosmolar with the influx of water. As the distal tubular permeability to urea increases distally, urea moves from an area of high concentration (the lumen) into an area of lower urea concentration (the interstitium) via the UT-1 urea transporters.[39] The interstitium becomes more hypertonic with the influx of urea, and the concentrating mechanism of the interstitium is partially restored.

Interstitium

Development

The tubular interstitium remains a poorly understood region of the kidney, both from developmental and functional standpoints. From a developmental perspective, the interstitium arises from cells that surround the ureteric bud and condensing mesenchyme and are possibly of mesenchymal origin. As the metanephros develops, the primordial interstitium differentiates to form the larger inner and outer medullary interstitium and the smaller cortical interstitium. In the inner medulla, the interstitium is involved in growth and branching of the collecting duct. In the outer medulla, the interstitium is involved in the elongation of the loops of Henle of the corticomedullary nephrons. Although the mechanisms for both processes remain unclear, the role of the interstitium appears to be in the promotion of growth/branching and attachment, respectively occurring through the secretion of growth factors and matrix proteins.[40]

Structure and Function

The interstitium is a composite of cells, fluid, matrix proteins, and fibrils that form a network supporting the function of tubules. In the cortex, the interstitium contains two dominant components: fibroblasts and dendritic cells. Cortical interstitial fibroblasts provide both structural support of the kidney and a synthetic role in the synthesis of erythropoietin.[41] The dendritic cells appear to originate from bone marrow and function largely in an immune capacity, presenting antigen in major histocompatibility complex (MHC) class II molecules to surveying cells of the immune system.[40,41] In the medulla, the interstitium is the site where the steep osmotic gradients are maintained. Additionally, some evidence supports a role for medullary interstitium in the secretion of vasodepressors. The role of these depressors, on either a local or systemic effect, requires further study.[40]

The interstitium is also a target of disease, with the result often being interstitial fibrosis. The development of interstitial fibrosis in response to injury is modulated by dendritic cell activity and subsequent cytokine release, as well as the synthesis of matrix by fibroblasts, most notably transforming growth factor β. A number of chronic inflammatory processes may induce chronic renal insufficiency through the development of interstitial fibrosis, a phenomenon that remains an area of active study.[41]

Summary

Structural development of the human kidney supports the observation that renal physiologic processes change with maturation. Perfusion, tubular function, and hormonal responses are unique in young patients and affect the renal response in health and disease. Understanding the functions of the pediatric kidney at various stages of development is important for predicting therapeutic responsiveness in the critically ill child and for monitoring recovery from illness.

CHAPTER 73

Fluid and Electrolyte Issues in Pediatric Critical Illness

Robert Lynch, Ellen Glenn Wood, Tara M. Neumayr

PEARLS

- Hypotonic maintenance IV fluids are associated with mild to moderate hyponatremia in postoperative patients. Anesthesia, stress, and inflammatory mediators probably contribute. Electrolyte monitoring in patients at risk is essential for detection and management of the occasional patient who develops severe hyponatremia. This critical effect of the syndrome of inappropriate antidiuretic hormone may occur even in patients on isotonic IV fluids.
- Medical patients with high levels of inflammatory mediators appear to be at increased risk of significant hyponatremia. Interleukin effects on antidiuretic hormone release may contribute.
- Albumin infusions have been generally safe but may introduce increased mortality risk in patients with traumatic brain injury. Those given albumin had increased intracranial pressure, which may contribute to the apparent risk.
- After septic patients achieve hemodynamic stabilization, avoiding or correcting excessive fluid volume overload will assist in liberating patients from ventilators and the intensive care unit.
- Proton pump inhibitors may cause hypomagnesemia, particularly in patients on concurrent diuretics. Although usually mild, this may be of significance in critically vulnerable patients.

Overview

Traditional fluid and electrolyte management in critical illness is being refined by science, observations of clinical experience, and expert opinion. Particular attention is drawn to intravenous fluid (IVF) composition, appropriate uses and choices of colloids, extracellular fluid (ECF) volume targets from resuscitation to maintenance,

and approaches to removal of excessive ECF volume using diuresis, continuous renal replacement therapy (CRRT), and intermittent hemodialysis (IHD).

Fluid and electrolyte management often begins at resuscitation, but important choices are also made at anesthesia induction and at initial postoperative maintenance. Resuscitative normal saline imposes an acid load, largely related to the chloride content.[1] Although physiologically effective and cost effective in almost all circumstances,[2] concerns regarding chloride toxicity warrant further clarification.[3] Similarly, intraoperative fluids influence acid-base and electrolyte status, particularly of vulnerable patients.[4] The choice of Na+ content and balancing ions of IVF for postoperative or critical care maintenance may be important for some patients thus justifying additional expense. Clearly 0.18 and 0.225 mM saline is associated with a higher incidence of mild hyponatremia,[5,6] although controlled trials do not show this effect for 0.46 mM saline.[7,8] Severe hyponatremia has been associated with pulmonary or CNS illness in pediatrics and is infrequent even within those categories, with the exception of children with traumatic brain injury (TBI). Among patients with those and other illnesses, the evolving study of the influence of inflammatory mediators directly on the hypothalamus and indirectly on vasopressin secretion may further clarify which patients are at most risk of clinically significant hyponatremia.[9,10]

Evidence for and against the use of colloids in specific groups of critical patients is accumulating. Intriguing but less than definitive studies suggest benefit in severe sepsis[11-14] and possible harm in patients with TBI, perhaps associated with increased intracranial pressure.[15] Consideration of albumin use in selected patients remains appropriate.[16,17] Albumin does appear useful in stabilizing patients with severe hepatic failure and in prevention of hepatorenal syndrome.[18-20]

Evidence for albumin use with or without diuresis among those with acute respiratory distress syndrome (ARDS) suggests improved oxygenation but minimal effect on outcomes.[21] In general, in patients with relatively intact vascular endothelium, 10 to 15 mL/kg of 4% or 5% albumin may be used for intravascular volume expansion with slower leakage into the ECF space compared to crystalloids. Albumin concentrate at 25% may be useful in temporarily redistributing ECF volume from the extravascular to the intravascular space to facilitate organ perfusion and spontaneous or drug-assisted diuresis with minimal additional infused fluid volume. There are currently no formulations of hydroxyethyl starch that can be recommended for use in critically ill patients.[22,23]

Adult and pediatric studies have raised concern regarding damaging effects of fluid volume overload particularly in patients with sepsis or ARDS.[24,25] Patients with less fluid gain early in their illness have more ventilator-free days and shorter ICU stays than those with greater than 10% to 15% early positive fluid balance. It remains unclear if mortality rates are affected.[26-29]

This effect of fluid volume on morbidity and perhaps mortality has led to proposals of a phased approach to fluid management including aggressive resuscitation using appropriate fluids guided by careful clinical measurement and evaluation, prompt reduction of resuscitation fluid rates when hemodynamically tolerated, gradual correction of volume excesses using fluid restriction, colloid dosing to adjust fluid space distribution, continuous infusion diuresis, and CRRT or IHD when needed.[30-33]

As ICU patients progress from stabilization to maintenance, ECF volume overload

may spontaneously resolve, or it may warrant active intervention due to the association of persisting major overload with increased morbidity. Loop diuretics do not prevent or ameliorate acute kidney injury[34] but may be useful in mobilizing excess ECF volume.[35] Studies of this measure are variable as to dosages, patient diagnoses, and renal conditions. Carefully titrated continuous infusion of loop diuretics may be superior to bolus dosing.[36-39] In ARDS, continuous infusion plus albumin have enhanced fluid mobilization.[40-42] Careful studies of approaches to fluid removal are needed. Accompanying loss of K+, Ca++, and Mg++ should be anticipated and replaced appropriately. For patients unresponsive to diuresis, either CRRT or IHD can provide electrolyte management and gradual ECF fluid correction[43-45] (see also Chapter 78).

Sodium

Sodium distribution is 90% extracellular and, with its associated anions, largely determines the osmotic condition of the extracellular fluid (ECF). Disturbance of ECF osmolality affects cell volume with critical clinical significance in the central nervous system (CNS). Neurologic symptoms, therefore, dominate the clinical picture in both hyponatremia and hypernatremia. In pediatric patients in the intensive care unit (ICU), young age, underlying neurologic conditions, developmental delay, cerebral hypoperfusion, and medication effects may obscure subtle neurologic findings, and judicious laboratory monitoring along with careful clinical assessment is essential.

Emerging evidence in both adult and pediatric patients suggests an association between disturbances in sodium balance and adverse outcomes, including mortality, ICU length of stay (LOS), use of both noninvasive and invasive mechanical ventilation, and long-term neurologic sequelae.[46-52] It is unclear at this time whether these adverse effects are a direct consequence of the sodium imbalance, are a reflection of a greater severity of illness, or are related to other underlying pathologic processes. Mild disturbances of sodium may serve as a warning of an ongoing process of greater significance. More severe hyponatremia or hypernatremia may be life threatening.[53] These disturbances may result from the disproportionate gain or loss of either sodium or water. Pathologic sodium retention may occur in disorders such as congestive heart failure (CHF), cirrhosis, and nephrotic syndrome without causing a significant change in ECF concentration, but the concomitant expansion of the ECF volume may be damaging.

Hyponatremia

Sudden, severe hyponatremia is life threatening, and its management demands prompt, measured action with ongoing monitoring and therapeutic adjustment. The syndrome of inappropriate antidiuretic hormone secretion (SIADH) and cerebral salt wasting (CSW) are the most common causes of severe hyponatremia, although gross feeding or iatrogenic misadventures also should be considered. Severe hyponatremia, which is variably defined as a serum sodium concentration of either <125 mEq/L or <120 mEq/L, is uncommon and is usually associated with known risk factors such as pulmonary or CNS disease or injury or the use of certain drugs. Mild hyponatremia is common among hospitalized pediatric patients and occurs

predictably in postoperative patients. Patients with renal, hepatic, or cardiac disease and those exposed to prolonged general anesthesia are particularly at risk. Accurate identification of patients at risk will inform decisions on frequency of laboratory monitoring and will allow an early evaluation of and response to evolving hyponatremia, whether related to water retention or sodium excretion.

Pathophysiology and Etiology

Hyponatremia may occur in the presence of decreased, increased, or normal amounts of total body sodium.

Decreased Total Body Sodium

Loss of total body sodium results in hyponatremia if total body water is retained in relative excess of the sodium loss. Hypovolemic stimulation of antidiuretic hormone (ADH) release may overwhelm osmotic ADH control, maintaining water retention despite hyponatremia and hypoosmolality. A decrease of as little as 5% in circulating volume may be sufficient to trigger this response.[54] Sodium deficit and volume loss may occur through extrarenal or renal losses. In children, extrarenal losses most often occur from vomiting and diarrhea. In critically ill patients, large extrarenal losses may result from fluid sequestration that occurs with septicemia, peritonitis, pancreatitis, ileus, rhabdomyolysis, ventriculostomy drains, and burns. Renal losses include diuretic use, osmotic diuresis, various salt-losing renal diseases, CSW, and adrenal insufficiency.[55]

Renal Sodium Losses

Renal salt-wasting states are generally identified by a urinary sodium excretion in excess of 20 mEq/L and a fractional excretion (FE_{Na}) of more than 1%. The use of thiazide diuretics can exacerbate hyponatremia and hypovolemia and lead to a characteristic hypokalemic metabolic alkalosis (ie, "contraction alkalosis"). In normally functioning kidneys, concentrated urine is produced by the equilibration of fluid in the collecting tubules with the hyperosmotic medullary interstitium, which in turn is generated by sodium chloride (NaCl) reabsorption without water in the ascending limb of the loop of Henle. Thiazides act in the cortical distal tubule and do not impair the ability of ADH to increase water reabsorption in the collecting tubules and collecting duct,[56] resulting in thiazide-associated hyponatremia. Osmotic sodium and water losses occur in a child with uncontrolled hyperglycemia with glucosuria, with mannitol use, and during urea diuresis following relief of urinary tract obstruction. Hyperglycemia and mannitol, in addition to inducing urinary sodium and water losses, produce osmotic water movement from the intracellular fluid (ICF) to the extracellular fluid (ECF), further lowering serum sodium. Sodium levels drop about 1.5 mEq/L for every 100 mg/dL rise in blood glucose level. Significant salt wasting may occur with several intrinsic renal diseases (Box 73.1). Adrenal insufficiency is distinguished by hyponatremia in association with hyperkalemia and decreased urinary potassium excretion.

Box 73.1

Causes of Hyponatremia

Decreased Total Body Sodium

Extrarenal

Vomiting/diarrhea

Sequestration: sepsis, peritonitis, pancreatitis, rhabdomyolysis, ileus

Cutaneous: burns, cystic fibrosis

Ventriculostomy drainage

Renal

Cerebral-renal salt wasting (CRSW)

Diuretics

Thiazides, loop diuretics (listed in order of severity of salt wasting)

Osmotic diuretic agents: mannitol, glucose, urea

Tubulointerstitial diseases

Cerebral Salt Wasting

Cerebral salt wasting (CSW) is a clinical entity that continues to generate controversy. First described by Peters and coworkers in 1950, it was superseded by the description of SIADH by Schwartz and coworkers in 1957 and then rediscovered in 1981 when Nelson and associates studied hyponatremia in a series of neurosurgical patients with isotopically measured low blood volumes.[57] Despite lingering skepticism, its distinct clinical identity continues to be supported (Table 73.1).[58-61] Patients typically have an acute neurologic injury with hemorrhage, trauma, infection, or a mass and may have undergone neurosurgical procedures. CSW differs from SIADH in that large urine volumes contain very high sodium concentrations, leading to rapid depletion of both sodium and ECF volume (Table 73.2). An otherwise unexplained intravascular volume contraction is central to the diagnosis and may cause a secondary boost in ADH release. Left untreated, CSW results in intravascular volume depletion, hypotension, and hypoperfusion or hypovolemic shock as well as hyponatremia. Untreated SIADH, in contrast, leads to progressive hyponatremia and the clinical consequences thereof with maintenance or mild expansion of fluid balance. The pathophysiologic link between intracranial injury and renal salt wasting has yet to be elucidated, contributing in no small part to the controversy. Both brain natriuretic peptide (BNP) and atrial natriuretic peptide (ANP) are attractive as potential mediators, but neither has a proved etiologic role.[62,63] Decreased sympathetic input to the kidneys is another postulated mechanism.[61] Distinguishing CSW from SIADH may be difficult in many complex clinical scenarios. In cases of severe or symptomatic hyponatremia, however, this may be temporarily unnecessary because the initial therapy is the same.[57] Administration of enough concentrated sodium to result in a small increase in osmolality is appropriate, and support of intravascular volume is required. A reasonable approach might begin with the administration of 5 mL/kg of hypertonic (3%) NaCl followed by isotonic repletion of the remaining volume deficit. Once this is achieved, sufficient sodium and fluid administration to account for daily maintenance requirements as well as ongoing losses is necessary. Administration of fludrocortisone, a mineralocorticoid, has been reported to aid in CSW management in severe or prolonged cases that are refractory to initial therapy.[61] In less severe cases, infusion of isotonic saline represents a reasonable first step in management, and the observed response may help to differentiate between CSW and SIADH. In CSW, saline administration addresses volume depletion and hyponatremia. It is of limited or no benefit in patients with SIADH, who are more effectively managed with fluid restriction.[59] Throughout, the absolutely essential part of therapy is the frequent reassessment of sodium levels and volume status with treatment adjustments as indicated.

TABLE 73.1

Cerebral-Renal Salt-Wasting Syndrome

Cerebral Salt	Wasting Syndrome
Trigger	Acute intracranial injury or illness (subarachnoid hemorrhage, trauma, etc.)
Onset	Typically a few days after the injury occurs
Signs	Falling serum Na^+, high urine output, high urine Na^+
Course	Without treatment, proceeds to intravascular volume depletion, hypotension, and hypoperfusion
Treatment	Replace salt and water losses; may require 3% NaCl +/− loop diuretics; fludrocortisone in refractory cases
Resolution	Days to weeks
Differential diagnosis	Syndrome of inappropriate antidiuretic hormone (SIADH), adrenal insufficiency, osmotic diuresis

TABLE 73.2

Cerebral Salt Wasting (CSW) Versus Syndrome of Inappropriate Antidiuretic Hormone (SIADH)

	CSW	SIADH
Urine Na^+	Very high, often >100 mEq/L	Variable, but usually >30 mEq/L
Urine output	Inappropriately high, leading to volume depletion	Variable; may be normal or decreased
Response to saline challenge	Improvement in volume deficit and serum Na^+	No improvement
Response to fluid and salt restriction	No improvement; volume deficit and hyponatremia may worsen	Improvement in serum Na^+

Increased Total Body Sodium

Hyponatremia with increased total body sodium occurs when the increase in total body water exceeds the sodium retention. Four clinical situations are commonly seen: congestive heart failure, cirrhosis, nephrotic syndrome, and advanced renal failure. In all four conditions, hyponatremia tends to be mild or moderate, asymptomatic, and nonprogressive or slowly progressive. These patients typically present to the ICU primarily for care related to these underlying conditions rather than for symptoms related to hyponatremia.

Congestive Heart Failure

Hyponatremia in heart failure is associated with a worse prognosis.[64,65] Low cardiac output states are characterized by a decrease in effective circulating volume that is detected by vasoreceptors in the carotid sinus, the aortic arch, and the renal juxtaglomerular apparatus. Activation of various neurohormonal modulators promotes vasoconstriction along with sodium and water retention. Increased sympathetic activity and stimulation of the renin-angiotensin-aldosterone system (RAAS) produce increased afferent and efferent arteriolar vascular resistance and decreased glomerular filtration rate (GFR) with a resultant decrease in urinary sodium excretion. Nonosmotic ADH release is stimulated, further impairing water excretion. In addition, decreased aldosterone degradation, along with altered levels of other vasoactive and nonvasoactive substances, leads to a primary increase in tubular sodium reabsorption. A deleterious positive feedback loop is created, in which the vasoconstrictive and fluid retentive effects of these neurohormonal systems promote further vasoconstriction and worsening renal perfusion.[66] The complex interactions between renal and cardiovascular pathophysiology have been described as the "cardiorenal syndromes" with five subtypes based on the primary organ affected and the acuity of the physiologic derangement.[67]

Cirrhosis

Early in cirrhosis, increased intrahepatic pressure may initiate renal sodium retention before ascites formation. The development of portal hypertension leads to nitric oxide–mediated peripheral vasodilation and to the formation of arteriovenous fistulae. The result is a decrease in effective circulating volume. These decompensated patients have higher levels of renin, aldosterone, ADH, and norepinephrine than do compensated patients with cirrhosis. Hyponatremia arises in the setting of persistent renal sodium and water retention.[68]

Nephrotic Syndrome

Hyponatremia is an occasional finding in patients with nephrotic syndrome. It may be present, however, in patients with apparently normal or decreased central volume. The humoral factors involved in patients with decreased central volume appear to be similar to those with decompensated cirrhosis.

Renal Failure

As a diseased kidney loses nephrons, the remaining nephrons exhibit a dramatically elevated fractional sodium excretion in efforts to maintain sodium balance. Edema develops when larger quantities of sodium are ingested than can be excreted. The ability to excrete water is also impaired, primarily because of the progressive decrease in GFR. Hyponatremia occurs when water intake exceeds insensible losses plus the maximum volume that can be excreted.

Normal Total Body Sodium

Hyponatremia without evidence of hypovolemia or edema in the pediatric population is usually associated with SIADH. Renal concentrating and diluting ability ultimately depends on the presence or absence of ADH to modulate water permeability in the collecting duct. Osmoreceptors for ADH reside in the anterior hypothalamus, responding to changes of as little as 1% in plasma osmolality. The nonosmotic stimuli that induce release of ADH are associated with changes in autonomic neural tone due to physical pain or trauma, emotional stress, hypoxia, cardiac failure, nausea and vomiting, adrenal insufficiency, volume depletion, and exposure to general anesthesia (Box 73.2). Nonosmotic stimuli, as the name implies, are active even in the face of normal plasma osmolality, and a decrease in plasma volume of as little as 5% is sufficient to trigger a strong ADH response.[54] Vasopressin (ADH) synthesized in the hypothalamus is transported in neurosecretory granules to the axonal bulbs in the median eminence and posterior pituitary gland and is released by exocytosis in the presence of appropriate stimuli. Increasing evidence indicates that inflammatory mediators facilitate release and contribute to the high incidence of hyponatremia in Rocky Mountain spotted fever, Kawasaki, and other inflammatory illnesses.[10] After release, ADH binds to V2 receptors in the basolateral membrane of the renal collecting duct, increasing cyclic adenosine 3′,5′-monophosphate formation and facilitating phosphorylation of aquaporin-2. Incorporation of aquaporin-2-containing vesicles in the apical (luminal) membrane increases cell permeability to water and provides a pathway for water reabsorption.[69]

General anesthesia

Marathon running or endurance exercise

Hereditary (gain-of-function mutations in the vasopressin V2 receptor)

Clinically, SIADH is characterized by (1) hyponatremia, (2) euvolemia or mild hypervolemia, (3) hypoosmolality, (4) inappropriately elevated urine osmolality, and (5) elevated urine sodium concentration. It has been associated with several categories of clinical disease, including CNS and pulmonary disorders, malignancies, and as an adverse effect of numerous drugs (Box 73.2).[70] Underlying renal function is normal. Under normal physiologic conditions, a decrease in serum sodium of 4 to 5 mEq/L below normal (with a serum osmolality of less than 270 mOsm) should maximally inhibit ADH secretion with a resultant urine osmolality of less than 100 mOsm. It is frequently difficult to determine, however, whether urine osmolality and urine sodium are inappropriately elevated, particularly in critically ill patients receiving IV fluids. Variable sodium and water administration rates, isotonic or hypertonic fluid boluses, fluctuations in hemodynamic status and urine output, and a history of diuretic use can all confound laboratory interpretation. The key consideration is the relative relationship between the degree of hyponatremia and hypoosmolality and the robustness of the dilutional response in the urine. Failure to maximally dilute urine in the face of hypoosmolality represents inappropriate ADH response so that a urine osmolality of 200 to 250 mOsm may reflect SIADH in hyponatremic patients. The urinary sodium level is generally more than 30 mEq/L but may be much less in patients who are provided a low sodium intake.[71] When the urinary sodium concentration is very high, it is the net balance between intake and output that differentiates between SIADH and a renal salt-wasting syndrome. Renal salt wasting is favored when the urinary sodium excretion grossly exceeds sodium intake.

Signs and Symptoms

The severity of signs and symptoms depends on the rapidity of the development of hyponatremia. Neurologic symptoms predominate as plasma hypoosmolality causes a shift in fluid from the ECF to the ICF compartment, leading to generalized cellular swelling. The rigidity of the intracranial space leaves little room for cellular expansion, resulting in increasing intracranial pressure. Brain cells prevent massive swelling in the early phases of hyponatremia by extrusion of electrolytes and other cellular osmolytes. Acute decreases in sodium concentration are associated with lethargy, apathy, and disorientation, often accompanied by nausea, vomiting, and muscle cramps. No predictable correlation exists between the degree of hyponatremia and its resultant symptoms, as severe hyponatremia that develops gradually may present with minimal symptoms. Acute decreases in sodium to less

than 120 mEq/L, however, generally produce severe symptoms such as seizures or coma. Other findings may include decreased deep tendon reflexes, pathologic reflexes, pseudobulbar palsy, and a Cheyne-Stokes respiratory pattern. Cerebral edema and intracranial hypertension may be severe enough to result in herniation, permanent neurologic injury, and death.[72]

Treatment

Prevention

Stimuli for ADH release are frequently present in both surgical and nonsurgical ICU patients, putting them at risk for hyponatremia. Use of hypotonic intravenous (IV) maintenance fluids increases the risk for development of hyponatremia. The appropriate administration of isotonic IV fluids in these patients will decrease the incidence of hyponatremia.[73-78] For patients with severe SIADH or CSW, however, the use of isotonic fluids alone may not be adequate to prevent life-threatening disturbances in sodium and water balance. Thoughtful monitoring of sodium levels along with avoidance of large volumes of hypotonic fluids is mandatory.

Therapy

The time course over which hyponatremia develops is a key determinant of the therapeutic approach. Severe hyponatremia is associated with significant morbidity and mortality and requires urgent attention. As described previously, acute hyponatremia produces significant cerebral edema when initial compensation mechanisms are overwhelmed and more chronic adaptive mechanisms are not yet fully developed. Hyponatremia that has been present less than 4 hours can safely be corrected promptly. When the evolution of hyponatremia is gradual, however, brain cells respond adaptively to prevent cerebral edema.

Thus there are two essential questions in constructing a therapeutic plan: (1) Did hyponatremia evolve rapidly or slowly, and (2) does the patient have CNS symptoms or imaging suggestive of cerebral edema? CNS cellular swelling and its symptoms are more likely with acute hyponatremia or with severe chronic hyponatremia.[79,80] Symptomatic hyponatremia that develops suddenly—that is, in fewer than 4 hours—can be rapidly reversed without incurring risk. If asymptomatic hyponatremia has developed over many hours, days, or weeks (ie, chronic hyponatremia), a gradual, conservative approach is likely to be uncomplicated. Symptomatic chronic hyponatremia, on the other hand, requires a small but rapid increase in serum sodium to stabilize or begin to reverse cerebral swelling and to avoid impending herniation, followed by a more gradual correction to normalize sodium balance. An increase of 5 mEq/L is usually sufficient to halt the progress of symptomatic cerebral edema and can be achieved with an initial bolus of 5 to 6 mL/kg of 3% saline. The subsequent correction rate for patients with either acute symptomatic hyponatremia or any chronic hyponatremia should not exceed 0.5 mEq/L/h. In acute hyponatremia without CNS symptoms, rates of 0.7 to 1 mEq/L/h have been reported without patient morbidity or mortality. A regimen of hypertonic 3% saline infused at 1 to 2 mL/kg/h with intermittent administration of a loop diuretic results in an appropriate correction for those patients for whom “rapid” correction is safe. Further correction may require isotonic fluids or a mixture of

isotonic and hypertonic fluids, particularly in patients with CSW. In resistant, severe CSW, mineralocorticoid (fludrocortisone) treatment has been helpful in several reports.[61,81,82] Other protocol approaches are available.[83]

Prolonged hyponatremia in animal studies is notable for a striking decrease in total brain amino acid content as well as lower brain water content.[84] When this brain cell adaptation has occurred, a rapid rise in serum sodium concentration may induce a shift of water from the ICF to the ECF compartment, resulting in brain dehydration, brain injury, and the osmotic demyelination syndrome (ODS).[85] Both central pontine and extrapontine myelinolysis have been reported in children.[86-89] Extrapontine sites include the cerebellum, thalamus, basal nuclei, hippocampus, midbrain, and subcortical white matter.[41] Traditional risk factors for ODS include chronic alcoholism, malnutrition, and rapid correction of hyponatremia.[90] Osmotic demyelination can occur, however, without hyponatremia as a starting point.[88,89,91] Large bolus doses of hypertonic saline may place the patient at risk regardless of starting sodium concentration. Electrolyte fluctuations around the time of liver transplantation may account for the risk of myelinolysis noted in these patients.[92] Rarely, ODS has been reported in patients with diabetic ketoacidosis but without hyponatremia on admission, including one case in an 18-month-old child.[87,89] Even rapid correction of hypernatremia is a possible cause of myelinolysis and suggests that pressure effects may be capable of causing damage to myelinated structures. Symptoms of osmotic demyelination may include obtundation, quadriplegia, pseudobulbar palsy, tremor, amnesia, seizures, and coma.[93,94] Classically, the clinical presentation is that of a brief period of recovery from encephalopathy followed by emergence of a "locked in" state or various movement disorders.[90] When CNS symptoms concerning for ODS emerge during therapy, long-term neurologic sequelae may be avoided by decreasing serum sodium to its nadir followed by a slower rate of correction.[95-97]

In cases of SIADH where fluid restriction is a feasible option, a decrease in fluid intake, occasionally with the use of oral sodium supplements, may be all that is required to normalize serum sodium gradually and safely. In a patient with hypovolemia, volume status clearly must be corrected in addition to the hyponatremia. Patients with SIADH or fluid-retaining states may respond to treatment with an ADH receptor antagonist. This receptor blocker group increases urine volume and reduces urine osmolality, creating a water diuresis that leads to an increase in serum sodium concentration.[98,99] Evidence for improvement in other clinical outcomes such as mortality or ICU length of stay, however, is currently lacking. Conivaptan is an intravenous ADH V1 and V2 receptor antagonist that is approved for the treatment of euvolemic and hypervolemic hyponatremia in adults.[100] Tolvaptan, an oral ADH V2 receptor antagonist, was approved in 2009 as therapy for euvolemic or hypervolemic hyponatremia in adult patients with heart failure, cirrhosis, or SIADH.[99] Pediatric usage of the ADH receptor blockers has been reported in the settings of SIADH and cardiac disease,[99-103] but further study of kinetics, safety, and efficacy will be needed to clarify the clinical role in pediatrics.

Hypernatremia

As with hyponatremia, hypernatremia can develop with low, normal, or high levels of total body sodium. History and weights are particularly important in evaluating

the hydration state of patients with hypernatremia because a shift in the ICF to the ECF tends to obscure the physical findings of dehydration. Accurate assessment of total body sodium and water aids considerably in planning management, although the most important management principle is the frequent monitoring of the patient's progress with treatment adjustments as needed.

Pathophysiology and Etiology

Low Total Body Sodium

Patients with a low total body sodium level have a loss of water in relative excess of sodium losses. Because the ECF space is hyperosmolar, water movement from the ICF occurs with resulting cellular dehydration. The ECF space, therefore, is somewhat preserved until an extreme degree of hypovolemia is present. Losses of sodium and water may be extrarenal or renal (see Box 73.3).

Box 73.3

Causes of Hypernatremia

Decreased Total Body Sodium

Renal

Diabetes insipidus (DI)

Central DI

Nephrogenic DI

Hypodipsia (reset osmostat)

Increased Total Body Sodium

Administration or ingestion of large sodium loads

Improperly diluted formula

In the pediatric patient, extrarenal losses are commonly seen from vomiting and diarrhea, although hospital-acquired hypernatremia from insufficient free water administration is a major concern.[104,105] Renal causes include osmotic diuresis from mannitol, hyperglycemia, or increased urea excretion. Infants are particularly susceptible to hypernatremic dehydration due to their high surface area/weight ratio and their relative renal immaturity, which necessitates greater water losses for excretion of a solute load compared with older children and adults.[106] Insufficient maternal lactation places young infants at risk of hypernatremic dehydration.

Normal Total Body Sodium

Loss of water occurs without excessive sodium losses in some conditions. Extrarenal losses include (1) increased respiratory losses as may occur with tachypnea, hyperventilation, or mechanical ventilation with inadequate humidification and (2) transcutaneous losses associated with fever, burns, extreme prematurity, or use of phototherapy or radiant warmers in the neonate without adequate water replacement. Renal losses result from congenital or acquired diabetes insipidus (DI), either central or nephrogenic. Acquired forms of DI are more commonly seen in the ICU. Major insults resulting in central DI include head trauma, tumors, infections, hypoxic brain injury, neurosurgical procedures, and nontraumatic brain death. Classically, in experimental animals and in humans, three stages occur: (1) an initial polyuric phase (hours to several days), (2) a period of antidiuresis probably due to ADH release from injured axons (hours to days), and (3) a second period of polyuria that may or may not resolve.[107,108] Sudden onset of polyuria is characteristic, and the conscious patient will often experience a concomitant polydipsia. In the critically ill patient, the inability to access increased water intake—whether from altered mental status, impaired thirst regulation, or other causes—may result in life-threatening hypernatremia.[109] Patients with the rare congenital forms of nephrogenic DI, resulting from X-linked alteration of the ADH V2 receptor or from autosomal recessive changes in the aquaporin II water channel itself, may have repeated bouts of hypernatremic dehydration.[110] Causes of DI are shown in Box 73.4.

Box 73.4

Causes of Diabetes Insipidus

Central

Congenital

Arginine vasopressin (AVP) antidiuretic hormone (ADH) gene mutations, autosomal dominant or (rarely) autosomal recessive inheritance

Dietary abnormalities

Primary polydipsia

Decreased sodium chloride intake

Severe protein restriction or depletion

Increased Total Body Sodium

Hypernatremia with an increased total body sodium level is most often an iatrogenic problem. In the ICU, hypertonic solutions of sodium bicarbonate are administered during resuscitation efforts or as therapy for intractable metabolic acidosis, excessive hypertonic saline administration, ingestion by infants of improperly diluted formula, and dialysis against a high sodium concentration. Normonatremic patients with massive edema who undergo a forced diuresis frequently become mildly hypernatremic because the induced urine may be hypotonic, with water loss exceeding sodium loss.

Hypernatremia is intentionally induced in patients with traumatic brain injury as a form of osmotherapy for control of intracranial hypertension associated with cerebral edema.[111,112] Such patients have tolerated serum sodium as high as 175 mEq/L when carefully managed. When the ECF osmolality of these patients is manipulated, the risks involved with rapid changes in either direction must be kept in mind (see also Chapter 119).

Signs and Symptoms

Clinical manifestations of hypernatremia, as is the case with hyponatremia, relate predominantly to the CNS. Marked irritability, a high-pitched cry, altered sensorium varying from lethargy to coma, increased muscle tone, and overt seizure activity may occur in children with the development of severe hypernatremia over 48 hours or more. Hyperglycemia and hypocalcemia also may occur. In infants with acute hypernatremia, vomiting, fever, respiratory distress, spasticity, tonic-clonic seizures, and coma are common. Death from respiratory failure occurred in experimental animals when serum osmolality approached 430 mOsm/kg.[113] Mortality in children with severe hypernatremia has ranged from 10% to 45% with chronic and acute hypernatremia, respectively.

Anatomic changes seen with the hyperosmolar state include loss of volume of brain cells with resultant tearing of cerebral vessels, capillary and venous congestion, subcortical or subarachnoid bleeding, and venous sinus thrombosis. During the first 4 hours of experimental acute hypernatremia, brain water significantly decreases, while the concentration of solutes (electrolytes and glucose) increases.[114] This leads to a partial restitution of brain volume within a few hours' time. Over several days, brain volume normalizes as a result of intracellular accumulation of organic osmolytes consisting of polyols, amino acids, and methylamines.[108,115]

Treatment

Whenever possible, therapy of hypernatremia should address correction of the underlying disease process as a primary goal. Correction of dehydration with slow hypernatremia correction is the target. When sodium exceeds 165 mEq/L, isotonic fluid or colloid may be used for correction of shock or circulatory collapse and initial reversal of hypernatremia. When hypernatremia has been present for more than a few hours, the presence of intracellular organic osmolytes dictates a slow rate of correction. Numerous fatal cases of cerebral edema and herniation have occurred with correction over a 24-hour period, leading to recommendations for correction over no less than 48 hours.[116,117] There is general agreement that plasma osmolality should not be decreased more rapidly than 2 mOsm/h, correlating with a rate of sodium decline that does not exceed 1 mEq/h. In cases of very severe or long-standing hypernatremia, a more conservative correction rate of 1 mOsm/h (0.5 mEq/hr of sodium) may be appropriate. Thus, normalization from extreme hypernatremia may take several days. This slower rate of correction appears to allow time for dissipation of the organic osmolytes without development of cerebral edema. Estimated deficits, ongoing maintenance requirements, and additional excessive losses must be accounted for in calculations of the amount of fluid replacement required.

Central DI is a likely cause of hypernatremia in an ICU patient with high urine volume and low urine osmolality, particularly in patients who have head trauma or who have undergone a recent intracranial operation. In these patients, a trial of vasopressin is in order. Either aqueous vasopressin given subcutaneously or intravenously (0.5 to 10 milliunits/kg/h) or 1-deamino-8-D-arginine vasopressin (DDAVP) given orally or intranasally may be used. Oral dosing is limited to tablet form at this time with a recommended dosing range of 0.05 to 0.4 mg administered twice daily. Intranasal DDAVP is generally begun in a dosage ranging from 0.05 to 0.1 mL once or twice daily. An increase in urine osmolality to values exceeding that in serum after vasopressin administration supports the diagnosis of central DI. Hyponatremia has been reported after vasopressin administration in patients with central DI as well as in patients receiving vasopressin for hemodynamic support and for bleeding disorders in the perioperative period.[118,119] In the outpatient setting, symptomatic hyponatremia, including seizures and altered mental status, has been reported in patients receiving DDAVP for enuresis, particularly in periods of intercurrent illness or with excess fluid intake.[120] Careful attention to the IV fluid prescription, serial monitoring of sodium levels, and timely adjustment in therapy are necessary to avoid severe complications in patients receiving any type of vasopressin therapy.

In patients with an increased total body sodium level and, often, hypervolemia, the goal is sodium removal. In patients with intact renal function, sodium removal may be accomplished with diuretics and a decrease in sodium administration. If renal failure is present, dialysis may be required.

Potassium

The total body K+ of about 50 mEq/kg is divided with about 98% being intracellular. The transmembrane concentration gradient is large with the intracellular

concentration of 150 mEq/L being maintained by sodium-potassium adenosine triphosphatase (Na+/K+-ATPase) pumps. The resultant transmembrane potential is normally tightly regulated but physiologically dynamic in contractile or conductive cells. Changes in extracellular or intracellular K+ concentration may alter the critical transmembrane potential of cardiac, skeletal, or smooth muscle cells with serious results.

Hypokalemia is relatively common in pediatric intensive care unit (PICU) patients but generally is detectable and manageable.[121] Severe hyperkalemia is much less frequent but much more likely to be life threatening with minimal warning.

Factors involved in total body distribution include acid-base status, insulin, catecholamines, magnesium, and aldosterone.[122-125] Acidemia tends to increase the serum potassium, and alkalemia lowers it. The type of acid-base disturbance (metabolic or respiratory), the duration of the disturbance, and the nature of the anion accompanying the hydrogen ion in metabolic acidosis are important in determining what effect a particular acid-base disorder may have on potassium concentration.

Diabetic ketoacidosis (DKA) may occasionally present with severe hypokalemia[126] due to losses. Hyperosmolality and decreased circulating insulin will preserve or even elevate serum K+ in most cases.[127,128] Epinephrine, albuterol,[129] and other beta-agonists decrease serum potassium, moving it into cells. β-adrenergic blocking drugs abolish this effect. Change in intracellular magnesium (Mg^{++}) may affect the sodium-potassium adenosine triphosphatase (ATPase) pump and alter the transcellular distribution. All of these mechanisms, however, are generally representative of fine-tuning in potassium homeostasis. Ultimately, potassium balance is regulated through excretion by the kidney and to a lesser extent the gastrointestinal (GI) tract. Massive cell lysis may overwhelm these and require aggressive management of the sudden shift of intracellular K into the ECF, particularly in the presence of compromised renal function.

Most of the filtered potassium is absorbed before the distal nephron in normal kidneys. The potassium excreted in the urine then is mainly due to secretion in the distal convoluted tubule and cortical collecting duct. As with sodium, the kidney's capacity to vary potassium excretion is profound, ranging from a low of approximately 5 mEq/L to amounts exceeding 100 mEq/L of urine. Factors influencing renal potassium excretion include mineralocorticoid and glucocorticoid hormones, acid-base balance, anion effects, tubular fluid flow rate, sodium intake, potassium intake, ICF and plasma potassium concentrations, and diuretics.[130] Aldosterone is a major kaliuretic hormone. Metabolic acidosis decreases and metabolic alkalosis increases intracellular potassium activity in cells of the distal tubule, causing enhanced potassium secretion during alkalosis and reabsorption during acidosis. Fluid delivery to the distal tubule probably enhances potassium secretion by two mechanisms: (1) the faster fluid moves past the secretory site, and a greater amount of potassium can be secreted, and (2) because tubular fluid potassium concentration decreases as flow rate increases, a favorable gradient for potassium movement is maintained at high flow rates.

Hypokalemia

Causes of Hypokalemia

Hypokalemia Without Potassium Deficit

The detection of a low serum potassium level may reflect a true deficit in total body stores or an apparent deficit from the shift of this ion from the ECF to the ICF pool. A shift to the ICF pool may occur in alkalemia,[131] administered or endogenous release of beta-agonist,[129,132] familial or thyrotoxic periodic paralysis,[133,134] barium poisoning,[135] and excess insulin. In the case of alkalemia, potassium moves into the cell in exchange for H+ in an attempt to maintain extracellular pH. The pediatric patient with alkalemia may have a true potassium deficit in addition due to decreased potassium intake or increased losses.

Periodic paralysis is a rare autosomal dominant disorder presenting with intermittent episodes of profound muscle weakness associated with a sudden fall in serum potassium concentration precipitated high-carbohydrate/low-potassium diet, exercise, infection, stress, or alcohol ingestion. Barium poisoning can produce hypokalemic weakness and paralysis, probably by competitive blockade of inward rectifying K+ channels. Insulin shifts potassium into muscle and liver cells in association with glycogen formation.

Hypokalemia With Potassium Deficit

A deficit in total body potassium may occur from decreased intake, from renal losses, or from GI losses. GI loss occurs with pyloric stenosis or other persistent vomiting, diarrhea, or binding of enteric K+ by ingested clay in patients with pica.[136]

Renal Losses

Major categories seen in the ICU include loop, thiazide, and osmotic diuretics, renal tubular acidosis, hyperaldosteronism, magnesium deficiency, and recovery from acute renal failure (ARF). Osmotic diuresis from glucosuria can cause severe renal potassium wasting in prolonged DKA predisposing to ventricular arrhythmia. The severity of K+ loss may be masked by the shift of potassium from the ICF to the ECF space related to insulin deficiency, metabolic acidosis, and hypertonicity.

Primary aldosteronism, congenital adrenal hyperplasia, adrenal adenoma, and familial idiopathic hyperaldosteronism[137,138] are rare in children and even rarer in the pediatric ICU setting. Secondary hyperaldosteronism is common, however, either from volume depletion or from CHF, cirrhosis, or nephrotic syndrome. Patients with the latter conditions, however, rarely have severe hypokalemia unless they are additionally treated with diuretics. Infants with Bartter or Gitelman syndrome[139] may initially come to the ICU because of multiple metabolic derangements including hypokalemia, metabolic alkalosis, hypomagnesemia, and hyperuricemia. Other findings include weakness, polyuria, and failure to thrive, with elevated renin and aldosterone levels in the absence of hypertension. Additional conditions associated with elevated renin secretion, secondary hyperaldosteronism, and hypokalemia include renal artery stenosis, malignant hypertension, renin-producing tumor, or Wilms tumor. Additional mechanisms include secondary hyperaldosteronism and increased distal tubular fluid delivery.

Other agents that induce excessive renal losses include amphotericin B (kaliuresis with reduced renal function and tubular injury); aminoglycosides, particularly gentamicin; and high-dose penicillin and carbenicillin, which produce an osmotic

load in addition to acting as non-reabsorbable anions. Renal tubular acidosis, hypomagnesemia, and caffeine toxicity may cause renal potassium wasting.[140-142]

Gastrointestinal Losses

Upper GI losses from vomiting or from nasogastric (NG) suction are frequently associated with hypokalemia. The gastric concentration of potassium ranges from 5 to 10 mEq/L. Concomitant volume depletion and metabolic alkalosis associated with NaCl and hydrogen ion losses often result in secondary aldosteronism, however, and an increased filtered load of bicarbonate with resultant renal potassium losses. Diarrhea, regardless of cause, may result in large potassium losses, the amount lost being related to the volume of fluid lost. Other GI causes are listed in Box 73.5.

Signs and Symptoms

For the intensivist, cardiovascular and neuromuscular effects of potassium deficiency are of particular concern, although metabolic, hormonal, and renal effects may also occur.

Electrocardiographic (ECG) changes include T-wave flattening or inversion, ST

depression, and the appearance of a U wave. Resting membrane potential is increased, as are both the duration of the action potential and the refractory period. The decreased conductivity predisposes to arrhythmias, as do increased threshold potential and automaticity.[143]

Hypokalemia diminishes skeletal muscular excitability. This can present as a dynamic ileus or a skeletal muscle weakness resembling Guillain-Barré syndrome. It can eventually affect the trunk and upper extremities, becoming severe enough to result in quadriplegia and respiratory failure.[144] Hypokalemia can lead to severe rhabdomyolysis in a variety of underlying conditions,[145-148] and may progress to ARF and hyperkalemia.[149] Autonomic insufficiency may also occur, generally manifested as orthostatic hypotension. In patients with severe liver disease, hypokalemia may precipitate or exacerbate encephalopathy. Glucose intolerance in the presence of primary hyperaldosteronism and in certain patients receiving thiazide diuretics has been corrected with potassium repletion. Renal effects of hypokalemia include polyuria and polydipsia, renal structural changes and functional deterioration with cellular vacuolization in the proximal tubule, and occasional interstitial fibrosis.

Treatment

Because of the wide spectrum of abnormalities resulting from marked potassium depletion, judicious correction is generally in order. In most pediatric ICUs, patients with cardiovascular disease are given NG or IV supplements at serum levels of 3 to 3.5 mEq/L. In the patient without life-threatening complications, the oral route is generally preferred for treatment, if possible, because this route is rarely associated with "overshoot" hyperkalemia if normal renal function exists. Oral dosage is frequently 1 mEq/kg up to a maximum of 20 mEq per dose, repeated if necessary. If, however, depletion is associated with digoxin use or with life-threatening complications, including cardiac arrhythmias, rhabdomyolysis, extreme weakness with quadriplegia, or respiratory distress, then urgent IV therapy is generally needed. Recommendations for IV dosage in the pediatric patient have ranged from infusions of 0.25 mEq/kg/hr to those as high as 1 to 2 mEq/kg/hr in the face of severe hypokalemia associated with DKA, arrhythmias, or quadriparesis and respiratory insufficiency. Ventricular tachycardia clearly associated with hypokalemia may initially require more rapid administration. Continuous ECG monitoring is essential, as well as frequent physical examination and determination of serum potassium levels to avoid hyperkalemic complications. Highly concentrated K solutions given IV should only be administered centrally. Patients who receive albuterol continuously are frequently mildly hypokalemic, but they rarely warrant potassium chloride replacement.

The potential for catastrophic drug error in replacing potassium is real. In most pediatric ICUs, patients with cardiovascular disease frequently require NG or IV supplements. Steps to decrease the chance of error include satellite pharmacy dosing, use of a mandatory drug request form, NG replacement when possible, use of a single solution concentration for all doses, and small aliquot solution containers. Continuing education regarding this risk for the pediatric ICU staff is essential.

Hyperkalemia

Causes

Hyperkalemia may result from artifactual elevation; from redistribution of potassium from ICF to ECF space; or from increased intake, decreased losses, or both (Box 73.6).

Box 73.6

Causes of Hyperkalemia

Artifactual

Ischemic potassium loss from muscle due to tourniquet use

In vitro hemolysis, profound leukocytosis, thrombocytosis

Drugs

Digoxin toxicity, β-blockers (b_2-inhibitory activity), succinylcholine, arginine, or lysine hydrochloride, chemotherapeutic agents, sodium fluoride, epsilon-amino caproic acid

True Potassium Excess

Increased Load

IV infusion, PO supplements, potassium-containing salt substitutes, potassium penicillin, blood transfusion

Redistribution and Tissue Necrosis

In vivo red cell injury

Change in pH

Hypertonicity

Burns, trauma, rhabdomyolysis, intravascular coagulation

Gastrointestinal bleeding

Urinary tract obstruction

Very-low-birth-weight infants

Inhibition of Tubular Secretion

Drugs

Spironolactone, triamterene, amiloride

Indomethacin, converting enzyme inhibitors, heparin, cyclosporine, tacrolimus trimethoprim, pentamidine, amphotericin B

Artifactual

Tight, prolonged tourniquet use produces spurious potassium elevation due to potassium release from ischemic muscle. Even more common is hemolysis of red cells with potassium release associated with capillary sampling or aspiration or delivery under pressure through a small needle. The lab may note hemolysis, but artifactual normality or actual elevation should always be considered.[150] Less commonly, in vitro release of potassium occurs from white blood cells (WBCs) (>100,000/uL) or platelets (>1,000,000/uL) and may result in increased levels.

Redistribution

In general, when extracellular pH falls, potassium exits from cells; the result is an

increase in serum potassium. As mentioned earlier, metabolic acidosis from mineral acids has a more pronounced effect than that of organic acids. Respiratory acidosis does not usually cause a marked change in potassium concentration.

Hypertonicity per se produces a shift of potassium from ICF to ECF. Studies of anephric animals show potassium increasing by 0.1 to 0.6 mEq/L for each increment of 10 mOsm/kg H_2O in tonicity. Hypertonicity causes cellular dehydration and therefore an increase in ICF potassium that favors increased passive diffusion out of cells. A very small percentage shift of IC potassium delivers a significant potassium load to the ECF. In the hyperkalemic patient in the ICU who has acute oliguria, mannitol should not be used for diuresis as further K+ elevation may result. In the patient with hyperglycemia, hypertonicity is likely only one of several mechanisms resulting in elevated serum levels.

Several commonly used drugs result in net movement of potassium from ICF to ECF. Digoxin inhibits the net uptake of K by cells by inhibiting Na/K-ATPase, with hyperkalemia commonly occurring in severe digitalis poisoning.[151] Other drugs include beta-blockers with β_2 activity and the muscle relaxant succinylcholine. This drug induces a prolonged dose-related increase in the ionic permeability of muscle, with subsequent efflux of potassium from muscle cells. Normal serum potassium concentration rises about 0.5 mEq/L. Succinylcholine should be avoided in patients with burns, muscle trauma, spinal injuries, certain neuromuscular diseases, near drowning, and closed head trauma, as up-regulated and new forms of acetylcholine receptors may respond with life-threatening hyperkalemia.[152] New examples of patients at risk will continue to be reported.[153,154] Hyperkalemia may result in nonsuspect patients via rhabdomyolysis or malignant hyperthermia following succinylcholine. Rhabdomyolysis has many causes including influenza, severe exercise, drugs, ischemia, and many more.[155-157] Familial hyperkalemic periodic paralysis appears to be related to potassium redistribution related to changes in ion channel function. Rebound hyperkalemia may be life threatening after coma-inducing barbiturate is stopped or surgical insulinoma removal.

Increased Load

Hyperkalemia due to an increased potassium load is unusual as long as renal function is normal. Serious elevations may be seen with inappropriate IV infusion, large volume blood transfusions,[158] bypass circuit initiation,[159] oral potassium supplements, salt substitutes containing potassium, or large doses of potassium penicillin. Strict measures to guard against accidental K overdoses are mandatory.[160] Large endogenous loads of potassium are more likely in the patient who is in the ICU. The release of cellular potassium associated with tissue necrosis from burns, trauma, rhabdomyolysis including that from spider bites[161] or the propofol syndrome,[162,163] massive intravascular coagulopathy, rapid hemolysis, or GI bleeding may lead to hyperkalemia.

Tumor lysis syndrome (TLS) is classically associated with drug or radiation treatment of sensitive lymphoid malignancies and results in hyperkalemia often accompanied by hypocalcemia, hyperphosphatemia, acidosis, and compromised renal function.[164] Many fatalities have been reported. The list of TLS-producing events or therapies includes transcatheter chemical and embolic tumor necrosis, monoclonal antibody treatment with rituximab, and enzyme-inhibiting agents

bortezomib, imatinib, and sorafinib. Cases have occurred in tumor patients with surgical stress or dexamethasone given for potential airway edema (see also Chapter 94).

Manifestations of Hyperkalemia

Life-threatening complications are most likely to result from the cardiac changes caused by hyperkalemia. ECG signs include tall, peaked T waves in the precordial leads, followed by a decrease in amplitude of the R wave, bradycardia, widened QRS complexes, prolonged PR intervals, and decreased amplitude and disappearance of the P wave.[165] Finally, the classic sine wave of hyperkalemia from the blending of the QRS complex with the P wave may appear. ECG changes do not necessarily correlate with specific levels of serum K+.[166] Realizing that ventricular arrhythmias or cardiac arrest may occur at any point in this progression and that progression may occur over a matter of minutes is extremely important.

Treatment

Treatment of hyperkalemia depends on the level of plasma potassium and the state of cardiac irritability.[47] If the potassium concentration is more than 6.5 mEq/L with associated ECG changes, additional measures are indicated. In the absence of digitalis toxicity, hyperkalemia with ECG changes should be treated with a secure and rapid IV infusion of calcium chloride or calcium gluconate. Hand injection with ECG monitoring is reasonable beginning with the administration of 10 mg/kg of calcium chloride (or gluconate equivalent) over 1 to 5 minutes. Infusion may be stopped if the electrocardiogram has normalized or if deterioration of the electrocardiogram seems to be precipitated by the potassium, suggesting a clinical scenario more complex than simple hyperkalemia. If the electrocardiogram improves but is not normalized by this calcium dose, additional calcium chloride may be given at a lower rate. It should be anticipated that ECG changes will recur in 15 to 30 minutes unless additional measures are taken immediately to treat the hyperkalemia. The effective calcium dose may be repeated as necessary to preserve cardiac function while additional treatments are in progress. Additional, rapidly effective treatments include nebulized albuterol (rapid neb or continuous neb of 0.3 to 0.5 mg/kg) or salbutamol (IV dose of 4 to 5 μg/kg over 20 minutes and repeated after 2 hours).[168,169]

Insulin and glucose are also rapidly helpful in redistributing potassium to the ICF. Glucose (1 g/kg) and insulin (0.2 U/g of glucose) may be given over 15 to 30 minutes and then infused continuously with a similar amount per hour. A premixed combination glucose and insulin solution has been successfully demonstrated in a 21 patient series.[170] Blood glucose monitoring is essential because the relative glucose and insulin amounts may need adjustment.

Sodium bicarbonate (1–2 mEq/kg given intravenously) has been a part of the classic treatment of hyperkalemia. Its benefit, however, is more difficult to predict and slower in onset than that of the measures mentioned earlier.

Sodium polystyrene sulfonate removes potassium and may be administered while dialysis arrangements are made. Sodium polystyrene sulfonate administered rectally must be retained for 15 to 30 minutes to be effective. If the oral route is available, it is

generally more efficient.

Hemodialysis is the treatment of choice for removal of K+ in emergent conditions. In the patient with severely compromised renal function, the measures above generally allow stabilization of potassium long enough to institute dialysis. Although hemodialysis is much more efficient for potassium removal than peritoneal dialysis, the latter may be more quickly instituted in many centers, particularly in the small infant in whom vascular access to support reasonable blood flow may be difficult to accomplish. In the absence of renal failure, loop diuretics or thiazide diuretics or both are useful for the increase of renal excretion. If mineralocorticoid activity is deficient, the administration of fludrocortisone may be indicated. In patients with severe hyperglycemia and moderate hyperkalemia, early steps to improve glucose control should decrease ECF potassium shifts from hyperosmolality and decrease ECF potassium shifts from hyperosmolality and decreased insulin.

If the potassium is less than 6.5 mEq/L without ECG changes, discontinuation of exogenous potassium and drugs that decrease its excretion with close follow-up of potassium levels may be all that is necessary. In the patient with renal compromise, extra potassium may be eliminated with use of the potassium-binding agent sodium polystyrene sulfonate (Kayexalate, resonium) (oral, NG, or rectal doses of 1 to 2 g/kg in a sorbitol or dextrose solution). When administered rectally, sorbitol may not be necessary, and it should certainly not be given rectally in concentration greater than 20%. Highly concentrated sorbitol may cause severe proctitis and colonic injury. Increasing reports of colonic injury particularly in hemodynamically compromised or premature patients suggest caution be exercised in using this preparation. However, when needed, having the pharmacy stock a premixed 10% to 20% suspension of sodium polystyrene sulfonate and sorbitol allows either oral or rectal administration on short notice.

Magnesium

Magnesium plays a key role in numerous metabolic processes, including cellular energy production, storage, and utilization involving adenosine triphosphate (ATP); the metabolism of protein, fat, and nucleic acids; and the maintenance of normal cell membrane function. It is also involved in neuromuscular transmission, cardiac excitability, and cardiovascular tone.[171]

Magnesium balance is maintained through intestinal absorption and renal excretion; 25% to 65% of ingested Mg is absorbed in the ileum. Absorption varies inversely with intake and is also affected by paracellular water reabsorption. Increased bowel water from any cause results in decreased magnesium absorption. Regulation of renal excretion occurs by glomerular filtration and reabsorption. The majority of filtered magnesium is reabsorbed in the ascending limb of the loop of Henle, resulting from active NaCl reabsorption and susceptible to loop diuretic inhibition. The threshold value for magnesium excretion varies between 1.5 and 2 mg/dL in different species. Thus if serum magnesium levels fall even slightly, renal excretion dramatically decreases under normal circumstances. Primary factors that increase renal magnesium excretion include ECF volume expansion; hypermagnesemia; hypercalcemia; metabolic acidosis; phosphate depletion; and various drugs including loop and osmotic diuretics, cisplatin, aminoglycosides,

cyclosporin, and digoxin. Decreased excretion occurs with ECF volume depletion, hypomagnesemia, hypocalcemia, hypothyroidism, and metabolic alkalosis to a lesser extent. Parathyroid hormone (PTH) may decrease magnesium excretion but that effect may be offset by the opposite effect of causing hypercalcemia.

Hypomagnesemia

Free, ionized magnesium and intracellular magnesium may be the critical concentrations, but determination of total magnesium is still clinically effective. Critically ill children have been reported to frequently have low ionized magnesium despite normal total magnesium levels.[172] Evidence supporting obligatory ionized magnesium measurement remains elusive.[173]

Magnesium depletion may result in hypocalcemia, via suppression of PTH secretion. Hypokalemia also occurs in patients with hypomagnesemia. Magnesium deficiency impairs the Na/K pump, allowing potassium loss from the ICF to the ECF and urinary excretion. Magnesium repletion is important to resolution of these secondary disturbances.

Causes

Intensivists deal with hypomagnesemia most often in patients receiving loop diuretics or transplant immunosuppressives.[174] Other causes must be considered.

Magnesium deficiency may be caused by decreased intake or increased losses. Although slight falls in serum magnesium levels may occur after 1 week of a deficient diet, a more sustained period of deprivation is generally necessary for significant hypomagnesemia to occur. In children, magnesium deficiency has been particularly common in protein-energy malnutrition and in anorexia nervosa, where refeeding syndrome is a particular risk.[175,176] Intestinal malabsorption is a major cause of magnesium deficiency. Isolated familial primary hypomagnesemia occurs from selective malabsorption of magnesium with patients generally having symptoms in infancy. These include tetany and convulsions as a result of severe hypomagnesemia with consequent hypocalcemia and respond well to supplemental magnesium. Other causes associated with magnesium malabsorption include regional enteritis, ulcerative colitis, massive small bowel resection, generalized malabsorption syndromes, pancreatic insufficiency, and cystic fibrosis. In some, the formation of insoluble soaps due to the complexing of magnesium with unabsorbed fat is the postulated mechanism for hypomagnesemia.

Increasing use of induced hypothermia may increase hypomagnesemia occurrence.[177] Epidermal growth factor blocking antibodies are associated with a small incidence of induced hypomagnesemia.[178,179] Hypomagnesemia may be more common than appreciated in patients presenting with hematologic malignancies.[180]

Intrinsic renal tubular disorders associated with hypomagnesemia are rare in the ICU setting (Box 73.7).

ADH, antidiuretic hormone; *GM-CSF*, granulocyte-macrophage colony-stimulating factor; *IVF*, intravascular fluid; *TPN*, total parenteral nutrition.

Drugs that induce renal magnesium wasting are more common causes and include aminoglycosides,[181] cisplatin,[182] amphotericin B,[183] diuretics,[184] cyclosporin A,[185] tacrolimus,[185] and proton pump inhibitors.[186,187] Magnesium supplementation is often needed in transplant recipients who receive cyclosporine or tacrolimus. Fractional excretion of magnesium and total excretion are elevated. Patients with DKA may also have marked renal magnesium wasting during the acidotic period, as well as in early treatment. An increased urine calcium level, from whatever cause, is often associated with magnesium wasting from competitive inhibition of renal tubular reabsorption of magnesium in the ascending limb.

Signs and Symptoms

In addition to biochemical derangements associated with hypomagnesemia, a wide spectrum of other clinical disorders has been attributed to its depletion, including cardiac arrhythmias, increased sensitivity to digoxin, coronary spasm, hypertension, seizures, and neuromuscular derangements. Hypomagnesemic arrhythmias include ventricular premature beats, ventricular tachycardia, torsades de pointes, and ventricular fibrillation.[188] Supraventricular arrhythmias are less common. Following magnesium infusion, improvement in resistant ventricular arrhythmias including torsades has been reported,[189] although other metabolic derangements often coexist in such patients. Magnesium deficiency enhances myocardial cell uptake of digoxin and toxicity. Both inhibit Na/K-ATPase with resultant ICF potassium depletion.

Depletion is thought to contribute to the development or worsening of hypertension by increasing vascular smooth muscle tone and reactivity. Increased cellular influx of calcium and decreased reuptake by sarcoplasmic reticula occur; the result is increased cytosolic calcium for activation of actin-myosin contractile proteins. Similar effects in coronary and cerebral vessels have also been observed.

Seizures may be the first symptom noted in an ICU setting. Other neuromuscular changes may include tremors, fasciculations, spontaneous carpopedal spasm, muscle cramps, paresthesias, seizures, and coma.[190,191,192] Personality changes, including apathetic behavior and depression, have also been associated.

Treatment

Patients undergoing or at immediate risk of hypomagnesemic malignant ventricular arrhythmias (such as torsades) or seizures can be given magnesium sulfate intravenously with careful monitoring. An IV infusion of 25 to 50 mg/kg per dose diluted to 10 mg/mL can be administered over 15 to 60 minutes. The rate of infusion should not exceed 150 mg/min. Doses may be repeated as needed depending on patient response. Complications of parenteral magnesium therapy include neuromuscular and respiratory depression, rare arrhythmias, flushing, hypotension, and prolonged bleeding times.[193] Other routes of therapy include intramuscular magnesium sulfate, injections of which are painful, and oral therapy with magnesium oxide or citrate. In situations known to be associated with the development of hypomagnesemia, it seems particularly important to attempt to avoid deficiency by adequate magnesium intake before development of life-threatening symptoms. The use of supplemental magnesium infusions in perinatal asphyxia[177] remains to be fully tested or extended to other hypoxic-ischemic encephalopathies.

Hypermagnesemia

Hypermagnesemia is less common than hypomagnesemia, but they can be life threatening when extreme.[194] Magnesium infusions in pediatric status asthmaticus have become common, despite remaining controversial in adult pulmonology.[195] Large doses clearly produce elevated blood levels,[196] but side effects are not common.

Cause

Hypermagnesemia occurs in patients with renal failure and is generally associated with iatrogenic administration of magnesium as antacids, cathartics, or enemas or through total parenteral nutrition (TPN) containing magnesium. In the absence of renal failure, the administration of large quantities of magnesium cathartics in the management of constipation[197] or overdoses[198] and antacid use with increased peritoneal absorption of magnesium in the presence of a perforated viscus[199] are causes. Magnesium levels as high as 10 to 12 mEq/L have been reported. Megadose vitamin-mineral supplementation, including magnesium oxide, has been fatal.[200]

Signs and Symptoms

Acute elevations of magnesium depress the CNS and the peripheral neuromuscular junction. Pseudocoma with fixed, dilated pupils has been reported. Deep tendon reflexes are depressed at levels greater than 4 mEq/L with total disappearance along with flaccid quadriplegia at levels greater than 8 to 10 mEq/L. Hypotension, hypoventilation, and cardiac arrhythmias may also occur.[201-204] Moderate hyperkalemia has resulted from prolonged magnesium infusions in occasional patients.

Treatment

Calcium acts as a direct antagonist to magnesium. In life-threatening situations

associated with severe magnesium intoxication, intravenous calcium should be used as the initial therapy. An initial dose of calcium chloride at 10 mg/kg or an equivalent amount of calcium gluconate has been suggested for infants and children. Magnesium-containing medications obviously should be discontinued. If renal function is normal, IV furosemide may be administered to increase magnesium excretion while urine output is replaced with half-normal saline. In patients with renal failure or severe toxicity, dialysis may be necessary for removal.

Calcium

Hypocalcemia is a common issue in pediatric critical care.[205,206] Hypercalcemia is an uncommon challenge in the PICU. Extracellular fluid (ECF) calcium concentration is best estimated with measurement of ionized calcium (Ca++) concentration. Total serum calcium includes physiologically accessible Ca++ plus that bound to protein or complexed with anions such as citrate of phosphate. The Ca++ concentration is under dual hormone control with PTH mobilizing Ca++ and calcitonin acting in bone and cartilage to retain fixed calcium. The concentration of Ca++ is particularly critical for cardiac, vasomotor, and neurologic function but is susceptible to disturbance by many factors including drugs, sepsis, major surgery, enteric disease, malignancy, pancreatitis, endocrinopathy, genetic misfortune, and many others.

Entry of Ca++ into cardiac and skeletal muscle cell mediates conversion of electrochemical into mechanical energy with resultant muscle contraction. Adenylate cyclase, phosphodiesterase and protein kinases are regulated by the interaction of Ca++ with calmodulin. A similar interaction stimulates myosin kinase in vascular smooth muscle so that Ca++ influx (enhanced by α-adrenergic and inhibited by β-adrenergic stimuli) causes vasoconstriction. Ca++ also plays a critical role in the clotting system and various membrane transport systems.

Extracellular Ca++ is monitored by Ca++-sensing receptors[207,208] on the surface of the chief cells of the parathyroid glands, the juxtaglomerular apparatus, the proximal tubule, the cortical thick ascending limb of the loop of Henle, the inner medullary collecting duct, the intestine, parts of the brain, thyroid C cells, breast cells, and the adrenal glands. Binding of Ca++ to this calcium sensor activates phospholipase C and the accumulation of inositol triphosphate, which leads to inhibition of the secretion and synthesis of PTH and inactivation of its proteolysis.

Regulation of Calcium

In the ICU, many changes in calcium activity result from changes in protein binding and chelation, excessive or deficient hormonal action, or excessive losses or intake of calcium. A majority of total serum calcium is bound to proteins, and this binding is pH dependent. Acidic pH decreases calcium binding and increases Ca++, whereas alkalemia increases binding and reduces Ca++. Blood products, renal failure, or massive cell lysis may result in increased chelation. Fortunately, direct measurement of Ca++ is now readily available in PICUs.

Hormonal Regulation of Calcium

Hormonal control of calcium homeostasis involves PTH, vitamin D, and calcitonin.

Secretion of PTH by the parathyroid chief cell varies inversely with the serum Ca++ and is inhibited by hypomagnesemia and 1,25(OH)2-vitamin D. Rapid proteolytic degradation of PTH yields a physiologically inactive C-terminal fragment and an active NH_2-terminal fragment. PTH binds to cell surface receptors in bone osteoblasts and kidney and exerts its effects through binding of a subunit of a membrane-associated heterotrimeric protein, which mediates increased formation of cyclic adenosine 3′,5′-monophosphate.

In the kidney, PTH inhibits proximal tubular phosphate reabsorption and promotes phosphaturia. This loss of phosphate inhibits bone mineralization and tends to shift the flow of calcium from bone to the ECF. PTH also increases distal tubular reabsorption of filtered calcium. PTH stimulates 1α-hydroxylation of 25(OH)-vitamin D, resulting in production of metabolically active 1,25(diOH)-vitamin D that stimulates intestinal absorption of calcium and phosphate. The overall effect of PTH is to raise serum calcium levels and lower serum phosphate levels. This characteristic reciprocal relationship is helpful in distinguishing PTH disorders from those involving vitamin D alone.[209]

Hyperphosphatemia lowers Ca++ by chelation, by shifting the equilibrium in calcium flux from ECF toward bone and by inhibiting 1α–hydroxylation activity. Calcitonin is a 32-amino acid, calcium-lowering hormone elaborated by C cells of the thyroid in response to rising Ca++ levels.[210] Although it rapidly reduces the bone resorptive function of osteoclasts and promotes calciuria and phosphaturia, its excess or absence causes no known disorder.

Hypocalcemia

Clinical and Laboratory Concerns

Hypocalcemia in pediatric critical illness may be associated with PTH deficiency, hypercalcitoninemia, or hypomagnesemia. Multiple mechanisms may act simultaneously. In children with severe burns, hypocalcemia, magnesium depletion, hypoparathyroidism, and renal resistance to PTH may all develop.

Cardiovascular manifestations are of particular ICU concern and may include hypotension, myocardial depression, CHF, and dysrhythmias. Cardiac contractility may be compromised acutely as in postoperative hypocalcemia. However, subacute cardiac myopathy from vitamin D deficiency and hypocalcemia may also be life threatening and reversible.[211-213]

Hypocalcemia inhibits acetylcholine release in both sensory and motor nerves. Accordingly, a variety of peripheral and CNS effects may result, including seizures, tetany, carpopedal spasms, muscle cramps and twitching, paresthesias, laryngeal stridor, and apnea in the newborn.

Somatic changes accompanying prolonged hypocalcemia include dry coarse skin, eczematous dermatitis, brittle hair with areas of alopecia, brittle nails with smooth transverse grooves, and dental enamel hypoplasia.

Determination of the free ionized Ca++ level is diagnostic, although the rate of decline also contributes to the development of symptoms. Estimations of Ca++ correcting for protein binding are not appropriate for managing critical illness.

The causes of hypocalcemia are summarized in Box 73.8.

Box 73–8

Causes of Hypocalcemia

Reduced PTH Effect

Parathyroid Gland Failure

Hypoparathyroidism—idiopathic or autoimmune

Colchicine

Theophylline

Ethylene glycol

EDTA, ethylenediamine tetraacetic acid.

Reduced PTH effect can result from parathyroid gland failure (autoimmune or surgical or radiotherapy thyroidectomy),[214-216] insensitivity to PTH (pseudohypoparathyroidism), or suppression of PTH release (hypomagnesemia, maternal hypocalcemia, burns). Hyperphosphatemia is frequently present. Clinical features may be distinguishing, but measurement of immunoreactive PTH is diagnostic.

Reduced vitamin D effect results from vitamin D deficiency seen in malabsorption in enteric diseases[217-219] or impaired conversion of 25(OH) to 1,25 (diOH) vitamin D seen in renal insufficiency. Certain drugs such as phenytoin can increase vitamin D metabolic degradation and cause deficiency.

Infusion of large amounts of citrate-preserved blood and acute phosphorus overload or retention can rapidly deplete ECF Ca++. Various drugs, particularly loop diuretics, also contribute to the development of hypocalcemia (see Box 73.8).[220-221]

Treatment

Correction of hypocalcemia should be preceded by consideration of readily treated or confounding factors such as respiratory alkalemia. Rapid development of hyperphosphatemia suggests acute renal failure, cell lysis, or excessive supply. As appropriate, efforts should be made to reduce serum phosphate levels, because intravenous calcium therapy may cause metastatic deposition of calcium phosphate salts. Hypomagnesemia impairs PTH release, response to PTH, and, consequently, correction of hypocalcemia. Hypomagnesemia may develop in critically ill patients by several mechanisms previously discussed.

Urgency of therapy is determined by the child's clinical status. Asymptomatic hypocalcemia is appropriately treated with oral calcium salts and vitamin D if needed. For the seriously ill patient with overt or evolving hypocalcemia, replacement therapy is accomplished with IV calcium chloride, 5 to 20 mg/kg, or an equivalent calcium gluconate infusion. Potential bradycardia and asystole with infusion of calcium should be anticipated with cardiac monitoring and atropine readily available. Care is required to prevent tissue damage by extravasation or

precipitation with concomitantly administered bicarbonate. In patients receiving digitalis, IV calcium is particularly dangerous as the arrhythmia potential is great. Hyperkalemia in digitalis toxicity should be treated with antidigitalis FAB therapy and not IV calcium infusion.

Oral administration of calcium salts is efficient for control of most persistent hypocalcemia and is preferable to prolonged infusion (although some patients with DiGeorge hypocalcemia require aggressive multi-modal treatment). Liberal amounts can be administered orally (eg, calcium 50 mg/kg/day in 4–5 divided doses), with attention paid to the differing calcium content of various oral preparations. For patients with fat malabsorption, supplementation of calcium therapy with magnesium or vitamin D may be needed. In the setting of hypoparathyroidism secondary to magnesium depletion, magnesium replenishment must occur.

Hypercalcemia

In contrast to dramatic manifestations of hypocalcemia, the effects of hypercalcemia may be subtle. However, a serum total calcium greater than 15 mg/dL represents a medical emergency. Renal, cardiovascular, and CNS disturbances predominate and reflect both the degree and duration of calcium elevation. Increased filtered load of calcium creates hypercalciuria and accompanying polyuria, reduced concentrating ability, dehydration, and eventual renal lithiasis. Hypertension is common, mediated through increased renin production and peripheral vasoconstriction. Alterations in the cardiac conduction system include a shortened QT interval and a tendency to dysrhythmias. Impaired nerve conduction creates hypotonia, hyporeflexia, and paresis in severe cases. Changes in CNS function include lethargy, confusion, and even coma. Constipation, anorexia, and abdominal pain resulting from reduced intestinal motility are frequent. Promotion of gastrin release by calcium may account for an increased incidence of peptic ulcer disease. Soft tissue deposition of calcium phosphate can impair function of lungs, kidneys, cardiac conduction tissue, blood vessels, and joints.

In the absence of hyperproteinemia, determination of elevated serum total calcium levels reliably indicates increased Ca++ concentrations. Because hyperparathyroidism and malignancies are less common in children, the pediatric intensivist encounters hypercalcemia less frequently. Diagnostic possibilities may be approached by considering the underlying mechanisms of hypercalcemia as outlined in Table 73.3.

TABLE 73.3

Tumor Lysis Syndrome

High risk	Lymphoid malignancies, large tumor mass, B-cell lymphoma concurrent renal compromise
Initiating event	Cytolytic chemotherapy
	Radiation therapy
	Embolic tumor infarction
Prophylaxis	Hydration, urinary alkalinization, allopurinol
	Gradual chemotherapy initiation, rasburicase
Serious disturbances	Hyperkalemia, hypocalcemia, acidosis, renal failure, hyperuricemia, hyperphosphatemia
Management	Obsessive electrolyte monitoring, Hemodialysis available stat, CVVHD helpful, may not be adequate

CVVHD, continuous venovenous hemodialysis; *stat*, immediately.

Increased bone resorption reflects excess PTH effect, immobilization, or bone lysis by metastatic malignancy. PTH-mediated hypercalcemia is distinguished by a depressed serum phosphate concentration, decreased renal tubular reabsorption of phosphate ($TmPO_4$/GFR), and an iPTH level inappropriately elevated for the simultaneous serum Ca++. In the child with hyperparathyroidism, evaluation for multiple endocrine neoplasias is warranted. Heightened vitamin D effect is manifested by increased intestinal calcium absorption and can be related to vitamin D intoxication,[222,223] increased sensitivity to vitamin D, or ectopically produced 1,25(diOH)-vitamin D, as seen in sarcoidosis. Serum phosphate levels and $TmPO_4$/GFR ratios are normal or increased, and iPTH levels are suppressed in these disorders. Detection of an elevated 25(OH)-vitamin D level may be helpful. High levels of vitamin A can also cause hypercalcemia and are particularly likely in patients with excessive intake or those with renal insufficiency.[224,225]

Decreased excretion of calcium occurs with dehydration or treatment with thiazide diuretics, aggravating the severity of hypercalcemia in hyperparathyroidism. Familial hypocalciuric hypercalcemia, an autosomal dominant disorder resulting from partially deactivating mutations in the Ca++-sensing receptor, is characterized by normal to slightly elevated iPTH levels and decreased urinary calcium excretion.[226] Thus determination of serum Ca++, phosphate, iPTH, vitamin D levels, and urinary calcium and phosphate excretion allows differentiation of most hypercalcemic disorders.

Treatment

A serum calcium level greater than 15 mg/dLc may be life threatening and requires direct Ca-lowering therapy in addition to attention to the underlying disorder. Hydration with isotonic saline (200 to 250 mL/kg/day) and furosemide diuresis results in calciuresis and amelioration of hypercalcemia in the majority of cases. Excessive losses of sodium, potassium, magnesium, and phosphate may require replacement.

Adjunct therapy is directed at the specific cause of hypercalcemia. Drugs that inhibit bone resorption include calcitonin (10 U/kg IV every 4–6 hours), mithramycin (25 mg/kg IV over 4 hours), and indomethacin (1 mg/kg/day). Recombinant calcitonin blocks PTH-induced bone resorption, facilitates calciuria, is relatively nontoxic, and has peak effect by 1 hour. Mithramycin is a toxic antibiotic that inhibits osteoclastic activity but has potential adverse effects including thrombocytopenia, hepatotoxicity, and renal injury. Indomethacin is useful when excessive prostaglandin E_2 production is suspected as in some cases of malignancy hypercalcemia.

Bisphosphonates have been used successfully in pediatrics for treatment of various disorders including hypercalcemia.[227-229] Corticosteroids are useful for treatment of vitamin D–related hypercalcemia, although the onset of action is not rapid.

Phosphorus

Virtually all of plasma phosphorus is in the inorganic form, with a small organic

component composed entirely of phospholipids bound to protein. Serum levels vary with age; approximate normal values (specific to the analytical instrument) are 4.8 to 8.2 mg/dL for neonates, 3.8 to 6.5 mg/dL for children aged 1 week to 3 years, 3.7 to 5.5 mg/dL for children aged 3 years to 12 years, and 2.9 to 5 mg/dL for adolescents aged 12 to 19 years.[230] Differences are thought to be related to more rapid rates of skeletal growth in the pediatric population. Most total body phosphorus resides in bone. As much as 60% to 80% of ingested phosphorus is absorbed, primarily in the jejunum. Absorption occurs by two pathways, one passive and one active. Passive paracellular transport is nonsaturable, so the greater the dietary intake, the higher is the net absorption. Active transport accounts for only 20% of total absorption via a vitamin D–dependent transporter, the Na-dependent phosphorus transporter 2b (NPT2b). Increased excretion of phosphorus from the kidneys after increased dietary intake is dependent on inhibition of the Na-phosphorus cotransporters 2a and 2c (NPT2a and NPT2c) in the luminal membrane of the proximal tubule. These transporters are inhibited from increased secretion of fibroblast growth factor 23 (FGF23). FGF23 is secreted by osteocytes and osteoblasts in response to oral phosphorus loading or an increase in serum 1,25 dihydroxy vitamin D levels. FGF23 induces an increase in the fractional excretion of phosphorus in the proximal tubule and decreases the efficiency of phosphorus absorption in the gut by lowering 1,25 vitamin D levels. PTH is also stimulated by increased intake of phosphorus by the fall in ionized calcium induced by transient hyperphosphatemia. Increased PTH causes a decrease in the expression of NPT2a and NPT2c in proximal tubules.[231] Absorption may also be decreased by a high calcium intake or by ingestion of antacids such as calcium carbonate or acetate, which bind phosphorus in the bowel. Glucose competitively inhibits phosphorus reabsorption. Glucocorticoids produce phosphaturia by a decrease in sodium-dependent transport in the proximal tubule.

Phosphorus plays an important role in cellular structure and function, bone mineralization, and urinary acid excretion. The development of severe phosphorus depletion affects the availability of intracellular ATP, depletes the erythrocyte of 2,3-diphosphoglycerate (2,3-DPG), with resultant tissue hypoxia, and impairs urinary acid excretion. The major acute effect of hyperphosphatemia is hypocalcemia; the long-term consequence is soft tissue calcification.[232]

Hypophosphatemia

Hypophosphatemia as measured by serum or plasma levels may or may not indicate true phosphorus deficiency. Severely depressed levels of serum-measurable phosphorus may occur in the absence of true deficiency after transcellular shifts from the ECF to the ICF, whereas a moderate phosphorus deficiency may be indicated only by slightly decreased serum levels.[233] Other processes that lead to true hypophosphatemia include increased excretion from the kidneys and decreased intestinal absorption. Hypophosphatemia may also result from a combination of these three mechanisms. Moderate hypophosphatemia has been defined as levels between 1.5 and 2.5 mg/dL and severe hypophosphatemia as levels less than 1.5 mg/dL on serum determination. In general, only with severe deficiency of phosphorus do multiple symptoms occur, as well as overt cell dysfunction or necrosis. Risk is greatest when superimposed additional cellular injury exists.

Cause of Severe Hypophosphatemia

Although numerous abnormalities may result in moderate decreases in phosphorus levels, severe hypophosphatemia has been associated with only a handful of clinical syndromes. These syndromes include significant respiratory alkalosis, prolonged use of phosphate-deficient TPN, the nutritional refeeding syndrome, thermal burns, DKA, pharmacologic binding of phosphorus in the gut, alcohol withdrawal, and several medications.[233-235] An association with continuous renal replacement therapy and bone recovery after renal transplant also has been reported.[236,237] The increase in the ICF pH associated with acute respiratory alkalosis stimulates the enzymes of glycolysis, with subsequent depletion of ICF phosphorus, which is replaced by an influx from the ECF space. Although carbon dioxide diffuses across membranes much more readily than bicarbonate does, metabolic alkalosis rarely produces a decrease in phosphorus levels, whereas very low levels may be seen with respiratory alkalosis.[238] An absolute deficiency from malnutrition and transcellular shifts from the ECF to the ICF with an anabolic response to increasing caloric intake are the causes associated with TPN use.[239] In the pediatric population, the preterm infant is particularly susceptible. Nearly 80% of calcium-phosphorus assimilation in the fetus occurs in the last trimester of pregnancy. The preterm infant is therefore born deficient in total body phosphorus. When reasonable nutrition has been absent for even short periods or when phosphorus has not been provided in TPN, severe hypophosphatemia has occurred, associated in several cases with the development of hypercalcemia.[240] A similar situation may occur with the refeeding of patients who have significant protein calorie malnutrition including anorexia patients.[241] As previously noted, an absolute phosphorus deficiency and transcellular shifts from the ECF to the ICF in the face of an anabolic response are responsible.

Significant hypophosphatemia in burn patients during their recovery phase has been associated with the presence of respiratory alkalosis, diuresis of initially retained sodium and water, and acceleration of glycolysis.[231,233] As previously described, ECF phosphorus shifts to the ICF compartment when intracellular-free phosphorus has been used in phosphorylation of organic compounds such as occurs during glycolysis, oxidative phosphorylation, glycogenolysis, and synthesis of glycogen, protein, and phosphocreatine. Acidosis decomposes organic compounds within the cell with subsequent movement of inorganic phosphorus from ICF to ECF and excretion in the urine. Osmotic diuresis augments these losses. Decreased intake also commonly occurs. During treatment of DKA, renal phosphorus clearance generally increases with fluid administration. In addition, insulin therapy results in stimulation of glycolysis and anabolism with a shift of phosphorus back to the ICF. If the acidosis has been present for only a few days, then rarely is there a severe phosphorus deficiency. Although levels may decrease, they generally return to normal without extra phosphorus therapy. In the patient whose symptoms have been present for a number of days to weeks, however, severe deficiency may exist at the time of admission. These patients may have life-threatening complications of hypophosphatemia if they are not treated. In general, this subset of patients has low phosphorus levels on admission, whereas phosphorus levels are normal or increased at admission in less severely affected patients. Patients undergoing continuous renal replacement therapy (CRRT) who become hypophosphatemic may be at higher risk for mortality.[242] In burn patients with >19% total body surface area burns, patients

receiving preemptive infusions of intravenous (IV) phosphorus beginning at 24 hours after injury had less hypophosphatemia and fewer complications versus those treated once hypophosphatemia developed.[243]

Signs and Symptoms

Multiple organ systems may be affected by severe hypophosphatemia, including CNS, cardiac, respiratory, musculoskeletal, hematologic, renal, and hepatic abnormalities.[244-251] Decreased diaphragmatic contractility in patients with hypophosphatemia with acute respiratory failure significantly improved as measured by transdiaphragmatic pressures during phrenic stimulation with treatment of hypophosphatemia.[252] Respiratory muscle weakness in patients with hypophosphatemia but with or without respiratory failure also has been documented and shown to normalize with phosphorus repletion.[248,250,251,253]

Neurologic symptoms may initially include irritability and apprehension followed by weakness, peripheral neuropathy with numbness, and paresthesias. Dysarthria, confusion, obtundation, seizures, and coma may occur in more profound cases.[246,249,254] Reports in the literature include Guillain-Barré–like syndrome,[255] diffuse slowing on electroencephalogram, and congestive cardiomyopathy[256] that significantly improved with correction of phosphorus depletion. In dogs, decreased cardiac output, decreased ventricular ejection velocity, and increased left ventricular end-diastolic pressure reversed with phosphorus repletion. In humans, rhabdomyolysis has been predominantly seen in alcoholic patients, in whom subtle myopathy was likely present, and rarely in patients with DKA or after TPN therapy. Decreased levels of 2,3-DPG in red blood cells (RBCs) may depress P-50 (oxygen half-saturation pressure) values so that the release of molecular oxygen to peripheral tissues is decreased, with resultant tissue hypoxia.[244] Structural defects of RBCs associated with hypophosphatemia have included rigidity and rarely hemolysis and have generally occurred when additional metabolic stresses such as metabolic acidosis or infection were placed on the RBC. Decreased levels of ATP in neutrophils may result in decreased chemotaxis, phagocytosis, and bacterial killing.[257] The mechanisms underlying the development of metabolic acidosis include decreased phosphorus excretion that thereby limits titratable acid excretion and decreased ammonia levels.

Treatment

As with other minerals and electrolytes, when oral therapy is potentially possible it is the preferable route for administration. In patients with severe hypophosphatemia, IV therapy is often indicated, though there remain no evidence-based recommendations for IV replacement.[258-260] Few data exist in the pediatric literature regarding dosage. Therefore most data are extrapolated from adult literature.[260-263] Reasonable recommendations in children with severe phosphorus depletion are to use 0.15 to 0.33 mmol/kg per dose, given as a continuous infusion over 4 to 6 hours. Subsequent doses are generally calculated on the basis of response to this initial dosage. Either potassium or sodium phosphate may be administered with the attendant potential complications of hypernatremia or hyperkalemia. A common recommendation is to use potassium phosphate if potassium (K) is <4

meq/L and sodium phosphate if the K is >4 meq/L. Other potential complications of therapy include hyperphosphatemia, metastatic deposition of calcium phosphate, hypocalcemia, potential nephrocalcinosis with renal failure, and hypotension. Both sodium and potassium phosphate contain 3 mmol of phosphate per mL and 4 or 4.5 mEq of sodium or potassium, respectively. For oral administration, a combination product of sodium with potassium phosphate (Neutra-Phos) has been used commonly in children. One capsule supplies 8 mmol of phosphorus along with 7.1 mEq of sodium and potassium. Capsules can be reconstituted in water as well. In infants the IV preparations may be used enterally with smaller volumes needed. Hypophosphatemia associated with continuous renal replacement therapy provides a special case. IV replacement is required in many such patients.[236]

Hyperphosphatemia

Causes of Hyperphosphatemia

Acute and chronic renal failure with decreased phosphorus excretion are the most common causes of hyperphosphatemia, with elevation in serum phosphorus occurring when the GFR is less than 30 mL/min/1.73 m^2. Extreme hyperphosphatemia associated with several deaths has been reported from the use of either oral sodium phosphate or enemas containing sodium phosphate in infants and children.[264,265] Abnormalities of intestinal anatomy or motility predisposing to retention of enemas or renal insufficiency represent risk factors, but no risk factors are identified in 30% of reported patients. Previous treatment does not guarantee safety with these agents, as 30% of reported patients had previously received enemas or oral therapy without complications. Average time to recognition has ranged from 12 minutes to 24 hours, with mean of 6.53 hours. Mean phosphorus levels were 27.9 mg/dL with plasma total calcium mean of 4.95 mg/dL. Unless there was kidney disease when older children and adolescents have also been affected, all reported patients have been <5 years of age.[264] The administration of IV boluses of sodium or potassium phosphate rather than slow infusion may result in symptomatic hyperphosphatemia. An error in parenteral nutrition resulted in hyperphosphatemia in multiple infants,[266] and severe hyperphosphatemia has been reported related to use of liposomal amphotericin B.[267]

Tumor lysis syndrome represents an additional cause of hyperphosphatemia along with hyperkalemia, acidosis, hypocalcemia, and renal failure. It results from induced lysis of tumor cells and is always a concern in a child with a lymphoid malignancy and substantial cellular mass, but it can occur in a variety of settings (see also Chapter 94). Initial chemotherapy or radiation of B-cell lymphoma is particularly likely to produce cell lysis and hyperphosphatemia along with hyperuricemia, acute renal failure (ARF), hyperkalemia, metabolic acidosis, and hypocalcemia. Aggressive hydration and careful initiation of chemotherapy usually will result in a manageable degree of electrolyte abnormality. Urinary alkalinization to increase urate solubility is usually recommended but is being reexamined. Rasburicase is replacing allopurinol in the control of urate levels. Hemodialysis or CRRT is an essential resource to have available if managing such a patient (see Table 73.2).

Signs and Symptoms

The major clinical consequence of severe hyperphosphatemia is its associated hypocalcemia, as well as soft tissue deposition of calcium phosphate salts. Seizures, coma, and cardiac arrest have been reported, generally in the presence of both hypocalcemia and hyperphosphatemia. In one case report, however, seizures, malignant ventricular arrhythmias, and cardiac arrest with acute hyperphosphatemia alone were described.[268] Hyperphosphatemia may be a proximate cause of ARF via precipitation in renal tissue.[269,270]

Treatment

In patients with life-threatening complications or multiple additional electrolyte disturbances or in the presence of renal failure, dialysis may be required. Intravenous fluid loading to increase renal phosphorus losses and intravenous calcium may increase excretion. Mannitol diuresis will inhibit proximal phosphorus reabsorption and theoretically should expedite phosphaturia. If oral administration is possible, Sevelamer has been used in patients with TLS to bind phosphorus and perhaps decrease the need for more invasive therapy.[271]

CHAPTER 74

Tests of Kidney Function in Children

Ayesa N. Mian, George J. Schwartz

PEARLS

- As a marker of glomerular function, serum creatinine provides a crude assessment because it is influenced by several factors other than glomerular filtration, of which the amount of muscle mass is clinically most significant.
- Serum cystatin C, another endogenous filtration marker not significantly affected by muscle mass, may provide a more accurate assessment of renal function, particularly in individuals with reduced muscle mass.
- Prediction formulas in children provide a better estimate of glomerular filtration rate (GFR) than serum creatinine alone because they incorporate surrogate variables for muscle mass.
- Current pediatric GFR estimating equations are not universally applicable. Appropriate use and interpretation of GFR prediction formulas require knowledge about the physiology of the marker, assays/auto-analyzers used to measure the marker, and characteristics of the population in whom the equation was developed.
- Neither serum creatinine nor the prediction formula is valid when renal function changes rapidly, yet both are used clinically, as better alternatives are not available. Changes in serum creatinine lag behind changes in GFR. It is essential to recognize that use of serum creatinine or creatinine-based equations in the setting of developing acute kidney injury (AKI) and before the establishment of a new steady state will result in an overestimation of GFR. Conversely, during the recovery phase of AKI, their use will result in an underestimation of GFR.
- Formal clearance studies are still clinically essential to assess renal function in select patients with atypical body habitus or diet.
- Novel biomarkers for AKI are still in the research phase but hold promise to facilitate earlier diagnosis of AKI, as well as to help distinguish among AKI phenotypes.

Renal dysfunction and injury are not unusual in the critically ill child and may

develop as a consequence of the underlying disease process (eg, hypoperfusion secondary to sepsis, progressive glomerulonephritis) or its therapy (eg, aminoglycoside toxicity). The ability to accurately, precisely, and rapidly assess renal function is essential for the early detection of acute kidney injury (AKI), for dose adjustments of medications excreted by or toxic to the kidney, in risk assessment for imaging studies involving intravenous contrast agents or gadolinium, and for monitoring for medication-related nephrotoxicity. AKI is now recognized to encompass a spectrum of disease ranging from mild, reversible, renal dysfunction to severe, potentially irreversible organ failure with need for dialysis support. In the past 10 to 15 years, standardized classification schemes for AKI based on an acute increase in serum creatinine or decrease in urine output [RIFLE (Risk, Injury, Failure, Loss, End-Stage Renal Disease); AKIN (Acute Kidney Injury Network); and KDIGO (Kidney Disease: Improving Global Outcomes)] have been proposed and validated in adults[1-3] with modified versions proposed for children[4,5] (Table 74.1). An increase in serum creatinine as small as 0.3 mg/dL is now well recognized to be associated with increased morbidity and mortality underscoring the need for precise, sensitive, and timely measures of renal function.[5,6] Notably, however, none of these definitions addresses AKI in the neonate. Jetton et al.[7] recently proposed a modification of the KDIGO classification for use in neonates (Table 74.2). The authors and others have found that preterm infants frequently experience a serum creatinine elevation of 0.3 mg/dL and that such increases can be associated with increased morbidity and mortality.[8] The true incidence of AKI in the pediatric intensive care unit (PICU) is not well established, but recent studies suggest it is increasing as advances in critical care medicine have led to improved patient survival and salvage of more critically ill individuals.[4,9] However, morbidity and mortality rates associated with AKI remain high.[4] Therapeutic intervention trials for AKI have had disappointing results in part related to delays in diagnosis, as well as the heterogeneity of patients enrolled.[10,11] The focus is therefore on earlier recognition and intervention for AKI, which should provide greater potential for recovery and/or stabilization of renal function. However, the early detection of incipient AKI is severely limited by the lack of sensitive and specific tools currently available to assess renal function.

TABLE 74.1
KDIGO Acute Kidney Injury Criteria

Stage	Change in Serum Creatinine	Urine Output
1	↑ ≥0.3 mg/dL over 48 h or ↑ 150%-200% over 7 days	<0.5 mL/kg/h for 8 h
2	↑ ≥200-300%	<0.5 mL/kg/h for 16 h
3	↑ ≥300%, S cr ≥4 mg/dL, or dialysis or eGFR ≤35 mL/min/1.73 m^2 for pts <18 yo	<0.5 mL/kg/h for 24 h or anuria for 12 h

From Kidney Disease: Improving Global Outcomes (KDIGO). Acute Kidney Injury Work Group. KDIGO clinical practice guidelines for acute kidney injury. Kidney Int Suppl. 2012;2:19.

TABLE 74.2
Proposed Neonatal Acute Kidney Injury Classification

Stage	Serum Creatinine	Urine Output
0	No change in S_{cr} or ↑ ≤0.3 mg/dL	≥0.5 mL/kg/h
1	S_{cr} ↑ ≥0.3 mg/dL within 48 h or ↑ ≥1.5-1.9 × reference S_{cr}[a] within 7 days	<0.5 mL/kg/h for 6-12 h
2		<0.5 mL/kg/h for ≥12 h

	$S_{cr}\uparrow$ ≥2-2.9 × reference S_{cr}[a]	
3	$S_{cr}\uparrow$ ≥3 × reference S_{cr}[a] or S_{cr} ≥2.5 mg/dL[b] or receipt of dialysis	<0.3 mL/kg/h for ≥24 h or anuria for ≥12 h

[a]Baseline S_{Cr} is defined as the lowest previous S_{cr} value.

[b]S_{Cr} value of 2.5 mg/dL represents <10 mL/min/1.73 m^2.

From Jetton JG and Askenazi DJ. Acute kidney injury in the neonate. Clin Perinatol. 2012;41:487-502.

Assessment of Glomerular Function and Injury

Glomerular filtration rate (GFR) is considered the best overall indicator of kidney function but remains challenging to accurately and efficiently measure in clinical practice. Functionally, the total kidney GFR is determined by the cumulative number of nephrons and the GFR within each nephron (single nephron glomerular filtration rate, or SNGFR). Conceptually, it represents the volume of plasma that could be completely cleared of a substance per unit of time. Kidney function may therefore decline due to hypoperfusion, resulting in a decrease in SNGFR, or due to nephron injury, resulting in fewer functioning nephrons; often both factors are present. The kidney has a certain degree of reserve and attempts to adapt to nephron loss by increasing the SNGFR of the remaining nephrons, thus maintaining total kidney GFR initially and masking early renal injury. Indeed, by the time the GFR actually falls, significant injury has already occurred. Loss of this renal reserve is one of the earliest manifestations of renal injury but is even more challenging to measure than GFR.[12-14]

Glomerular filtration is a dynamic variable that can fluctuate in a given individual by as much as 7% to 8% from day to day on the basis of differences in hydration status, activity, and protein consumption.[15,16] GFR is also influenced by age, gender, and body size and therefore varies between individuals as well. Therefore to facilitate comparison of GFR among children and adults of considerably different size, absolute GFR is normalized to body surface area (BSA), which correlates well with kidney weight, the most direct standard of reference.[17] Appreciation of the maturational increase in GFR that occurs during infancy is also necessary for proper assessment of kidney function in children. At birth, the mean GFR is quite low (20 mL/min/1.73 m^2 in term infants) due to renal immaturity yet sufficient to meet the metabolic demands of a healthy infant. The GFR doubles within the first 2 weeks of life and then continues to gradually increase to reach a mean of 77 mL/min/1.73 m^2 between 1 and 6 months of age and adult levels of 120 to 130 mL/min/1.73 m^2 by approximately 2 years of age (Table 74.3).[18]

TABLE 74.3

Normal Glomerular Filtration Rate Values for Children

Age	GFR (mL/min/1.73 m^2)	Range (mL/min/1.73 m^2)
Preterm (<34 wk)		
2-8 days	11	11-15
4-28 days	20	15-28
30-90 days	50	40-65
Term (>34 wk)		
2-8 days	39	17-60
4-28 days	47	26-68
30-90 days	58	30-86
1-6 mo	77	39-114

6-12 mo	103	49-157
12-19 mo	127	62-191
2-12 yr	127	89-165

Modified from Heilbron DC, Holliday MA, al-Dahwi A, et al. Expressing glomerular filtration rate in children. Pediatr Nephrol. 1991;5:5-11.

GFR itself cannot be directly measured but can be assessed by measuring the clearance of an ideal filtration marker or estimated using predictive formulas. Urinary or plasma clearance studies provide the greatest accuracy but are expensive, time consuming, and labor intensive. Consequently, they are used mainly for research and in select clinical situations where an accurate assessment of kidney function is necessary (eg, chemotherapy dosing). For the daily clinical management of patients, serum creatinine and GFR estimating equations are used most commonly. They offer the advantage of being convenient, noninvasive, and inexpensive with timely accessibility of results. However, accuracy and sensitivity to small changes in renal function are sacrificed, making the detection of acute, early renal dysfunction difficult. The search for novel biomarkers of renal function (such as cystatin C) and early renal injury (eg, neutrophil gelatinase-associated lipocalin [NGAL]) has therefore been a major focus in the field of AKI.

Renal Clearance Techniques

Inulin

The renal clearance of inulin remains the gold standard for measuring GFR. Inulin is an inert, uncharged 5.2-kDa polymer of fructose that possesses many characteristics of an ideal filtration marker. It is not protein bound and is freely filtered at the glomerulus without being reabsorbed, secreted, or metabolized by the kidney. Further, it is eliminated exclusively by the kidney.[19] In the steady state the filtered load of inulin (GFR × P_{in}) is therefore equal to its urinary excretion (U_{in} × V) where P_{in} and U_{in} are the plasma and urine concentrations of inulin (mg/dL), respectively, and V is the urine flow rate (mL/min). The renal clearance of inulin (C_{in}) can be calculated:

$$C_{in} = GFR = (U_{in} \times V)/P_{in} \qquad \textbf{Eq. 74.1}$$

C_{in} is usually scaled for BSA:

$$C_{in} = GFR = [(U_{in} \times V)/P_{in}] \times [1.73\ m^2/BSA] \qquad \textbf{Eq. 74.2}$$

The classic protocol for inulin clearance is cumbersome, involving an intravenous infusion of inulin over several hours and serial timed blood and urine specimens. Properly done, inulin clearances provide the most accurate measure of GFR; however, the complexity of the protocol introduces a potential for significant error. Incomplete urine collections diminish the accuracy of the test and can be particularly problematic in children who are not yet toilet-trained or who have urologic disease (eg, vesicoureteral reflux, bladder dyssynergia) affecting their ability to

spontaneously void to completion. Placement of a bladder catheter or use of a bladder scanner may improve accuracy, although the former may pose a small risk of infection and the latter may be of limited benefit in children with vesicoureteral reflux. Limited availability of inulin, technical issues pertaining to its assay, and the laborious nature of the protocol make it impractical for routine clinical use.

Iothalamate

Iothalamate (614 Da) is also freely filtered by the glomerulus and has been studied extensively as an alternative exogenous marker for GFR measurements. Unlike inulin, however, iothalamate has some protein binding (<8%) and proximal tubular secretion (10%), raising concern for overestimation of GFR. Reported correlations between iothalamate and inulin renal clearances in the literature have been variable, with some studies demonstrating good correlation, whereas most suggest that iothalamate overestimates inulin clearance.[20-22]

Creatinine Clearance

Clearance studies that make use of endogenous markers such as serum creatinine obviate the need for a constant infusion and make the study more amenable to clinical practice. However, the problems associated with timed urine collections persist and accordingly limit the usefulness of this technique, particularly in children. Further, creatinine is a flawed filtration marker. Although it is predominantly eliminated by glomerular filtration, a small but variable amount (~10%) is eliminated by tubular secretion. As renal function deteriorates, the proportion of secreted to filtered creatinine progressively increases, leading to an overestimation of GFR and a less reliable measure of GFR.[16] Administration of oral cimetidine beginning 2 days before the study can at least partially circumvent this issue by inhibiting the tubular secretion of creatinine.[23] Although timed urine collections are still necessary, they are typically obtained over a 2-hour period facilitating performance in a monitored clinic setting.

Guidelines from the National Kidney Foundation no longer recommend routine performance of creatinine clearance studies to estimate GFR, as prediction formulas are considered more accurate.[24] Nonetheless, creatinine clearance-based studies can still be helpful when assessing renal function in individuals with atypical body composition (eg, anorexia, malnutrition) or dietary intake (eg, vegetarian diet).[24,25]

Plasma Disappearance Techniques

Plasma disappearance techniques further simplify the measurement of GFR and avoid the need for urine collections. They are most commonly performed using a single intravenous injection technique, although constant infusion and subcutaneous protocols are also available.[20,26,27] Serial blood samples collected at specified times over a several-hour period following injection of the filtration marker are used to generate a plasma disappearance curve. This curve can be well approximated by a double exponential curve that is characterized by an initial “fast” curve and a later “slow” curve as illustrated in Fig. 74.1. The initial “fast” curve represents the distribution phase and reflects renal elimination, as well as diffusion of the marker

into the extravascular space, whereas the late "slow" curve reflects only the renal elimination phase. Renal clearance can be calculated by dividing the delivered dose by the entire area under the plasma disappearance curve.[28] Modification from a two-compartment model to a one-compartment model focusing on the renal elimination phase simplifies the procedure, reducing the number of required blood specimens to two. GFR can then be derived from the slope of the slow curve but requires incorporation of a correction factor to compensate for overestimation of the GFR, which results from exclusion of the area under the fast curve.[28-31] Appropriate timing of the specimens is critical to ensure an accurate estimation of GFR. The first sample must be obtained after the marker has equilibrated, typically 2 hours after injection. The second specimen is obtained approximately 5 hours after injection, but in subjects with more advanced chronic kidney disease (CKD), this may need to be delayed further to minimize overestimation of the GFR, which can result from an inaccurate depiction of the lower slope of the plasma disappearance curve.[30] The validity of the single-compartment model may also be compromised in edematous states where the volume of distribution is increased, or with extravasation of the tracer at the injection site, as this decreases the actual dose delivered.[29] Although plasma disappearance studies are time consuming and too complex for routine clinical care, they are useful in cases for which GFR estimates do not appear to be accurate.

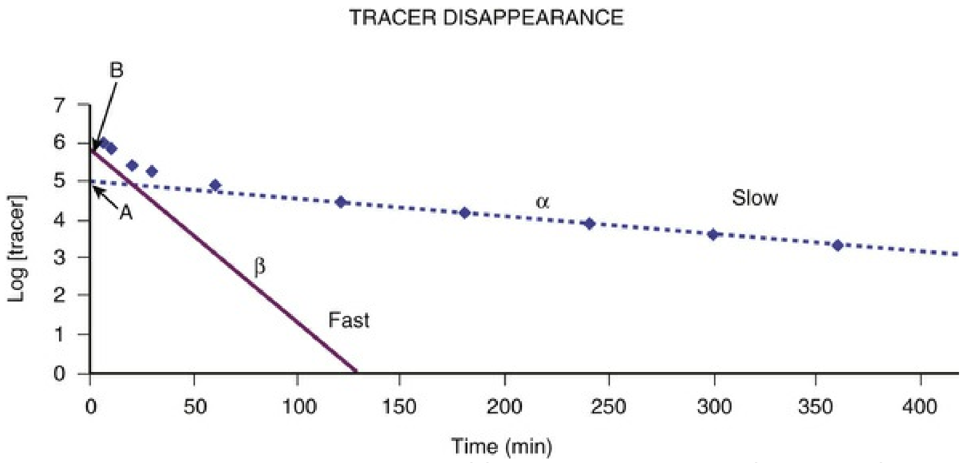

FIG. 74.1 Plasma disappearance of filtration marker as a function of time after injection into blood. The curve is composed of two components: the slow curve with slope α and intercept A and the fast curve with slope β and intercept B. (Modified from Schwartz GJ, Furth SL. Glomerular filtration rate measurement and estimation in chronic kidney disease. Pediatr Nephrol. 2007;22:1839-1848.)

Radioisotopes

Plasma clearance studies are most commonly performed with radioisotopes that are more readily available and easier to assay than inulin. Their major disadvantage is, of course, radiation exposure, which limits their use, particularly in children.[32] ^{51}Cr-ethylenediaminetetraacetic acid (EDTA), ^{99m}Tc-DTPA, and ^{125}I-Iothalamate have been extensively studied and compared with inulin renal clearance.[20,33] All are low-molecular-weight compounds that are freely filtered by the glomerulus but differ

slightly in protein binding and renal disposition. ^{51}Cr-EDTA (292 Da) appears to have little protein binding, and its plasma clearance correlates well with inulin clearances. It is commonly used in Europe but unavailable in the United States.[30] ^{99m}Tc-DTPA (393 Da) is most frequently used in the United States but demonstrates variable accuracy in GFR measurements on the basis of product source, differences in protein binding, and potential dissociation of the chelate ($t_{1/2}$ = 6 hours) during the study.[34] ^{125}I-Iothalamate (614 Da) is a high-osmolar anionic contrast agent with some protein binding that also undergoes active secretion by the proximal tubule, contributing to overestimation of plasma clearance compared with inulin or EDTA.[22] Nuclear GFR studies can also be performed using a gamma camera, which measures the renal uptake of the tracer 2 to 3 minutes after injection and can provide information regarding differential kidney function; however, the estimated GFR obtained this way is not as accurate as with the plasma-sampling technique.[30] To reduce radiation exposure, plasma clearance studies can also be performed using nonradiolabeled iothalamate, which can be measured by high-performance liquid chromatography (HPLC).[35,36]

Iohexol

Iohexol is now widely accepted as an excellent alternative to inulin and radioisotopes for clearance studies. Iohexol (Omnipaque) is a low-molecular-weight (821 Da), nonionic, relatively low-osmolar intravenous contrast agent used routinely in the United States for radiologic studies at doses appreciably higher than that required for GFR studies.[37,38] It is almost entirely eliminated through glomerular filtration and is not reabsorbed, secreted, or metabolized by the kidney, thus fulfilling many of the desired traits of an ideal filtration marker. Further, it has minimal protein binding and negligible extrarenal elimination even in advanced chronic kidney failure.[37,39] It can easily be measured by high-performance liquid chromatography or mass spectroscopy.[38,40-42] Iohexol has been safely used for clearance studies for many years in Scandinavia[37,43,44] and the United States.[31,45] Iohexol plasma clearance results appear to be comparable with renal inulin clearance and plasma EDTA disappearance studies across a broad range of GFR.[38,46,47] Schwartz et al.[48,49] recently demonstrated the feasibility of conducting iohexol clearance studies using the finger prick technique with filter paper technology in adults, a procedure which would alleviate the need for repeated venipunctures or placement of a second IV from which to collect serum samples making it attractive for use in children.[48] However, additional studies are necessary before it is ready for widespread clinical use.

Renal Inulin Clearance Compared With Other GFR Measurement Techniques

Soveri et al.[50] recently performed a comprehensive, systematic literature review examining the accuracy of GFR measurement techniques using renal inulin clearance as the gold standard. The renal clearance of EDTA and iothalamate, as well as the plasma disappearance of EDTA and iohexol, were considered suitable alternatives with an associated bias less than 10% (mean difference between renal inulin

clearance and that obtained using other techniques), P_{30} >80% and P_{10} >50% (percentage of GFR measurements within 30% and 10%, respectively, of inulin GFR). Creatinine clearance was not accurate and there was insufficient data to accurately assess the use of the plasma clearance of DTPA.[50]

Plasma Markers

Creatinine

Serum creatinine is the most commonly used laboratory study to assess renal function in clinical practice. It is simple, convenient, and practical—requiring a single blood sample—and therefore well suited for serial examination. However, the relationship between serum creatinine and GFR is quite complex, being influenced by several factors other than GFR. Therefore, at best, creatinine provides a crude estimate of the GFR. As illustrated in Fig. 74.2, serum creatinine bears an inverse, nonlinear relationship with GFR and lacks sensitivity to acute and small changes in GFR. Notably, at low levels of serum creatinine corresponding to normal renal function, a substantial decrease in GFR may occur before being reflected by even a small increase in serum creatinine. In contrast, at higher levels of serum creatinine associated with renal failure, the same absolute rise in creatinine reflects a much smaller loss of remaining renal function. To a first approximation, every doubling of the serum creatinine represents a 50% decline in remaining GFR.

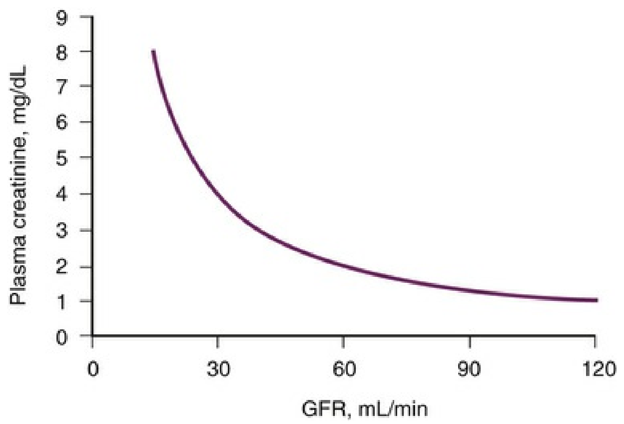

FIG. 74.2 Idealized relation between the steady-state levels of serum creatinine and glomerular filtration rate (GFR) in adults. When renal function is normal, a marked decrease in GFR can be associated with only a mild increase in serum creatinine.

Ideally, an endogenous marker such as creatinine can serve as a useful surrogate for GFR if it is produced at a constant rate and eliminated only via the kidney at a rate equivalent to its production rate such that a steady state exists. Fig. 74.3 illustrates the relationship between the plasma level of an endogenous filtration marker, its generation (from cells and diet), and its elimination (renal and extrarenal). The serum level of the marker would then be expected to rise with renal impairment. Serum creatinine, however, does not strictly fulfill these criteria. Although creatinine production is relatively constant, it varies among and within

individuals.[51] It is derived from the nonenzymatic dehydration of muscle creatine and hence is highly dependent on muscle mass. Consequently, in children, creatinine generation is affected by growth in addition to diet and illness, as seen with adults.[51] The reference range for serum creatinine levels representing normal GFR will thus vary with age, size, and gender after puberty. The relationship between GFR and serum creatinine is therefore particularly complex in children. Maturational changes in serum creatinine and GFR do not parallel one another. GFR is physiologically low at birth, whereas serum creatinine is elevated; however, because of fetal-maternal-placental equilibration of creatinine, the elevated creatinine is not indicative of the infant's renal function but rather the mother's. Following birth, GFR steadily increases, reaching adult levels over the next 2 years. Serum creatinine, on the other hand, declines over the first few weeks, becoming reflective of the infant's renal function. The creatinine level then remains stable until approximately 2 years of age as muscle mass accrues proportionally to the increase in GFR. Beyond 2 years of age, when GFR per BSA has fully matured, the ongoing accretion of muscle results in a progressive rise in serum creatinine until adolescence, when adult levels are achieved (0.7 mg/dL for adolescent females and 0.9 mg/dL for adolescent males). Superimposition of a severe or chronic illness associated with malnutrition and muscle wasting makes the interpretation of GFR from serum creatinine alone even more difficult in the pediatric patient. For example, at first glance, maintenance of a stable creatinine in a patient with a prolonged ICU course may be reassuring for preservation of renal function; however, if significant muscle atrophy has occurred, this actually suggests deterioration of renal function. In the steady state when height is used as a surrogate for growth, there is a strong correlation of the parameter Ht/S_{Cr} and GFR.[52-54]

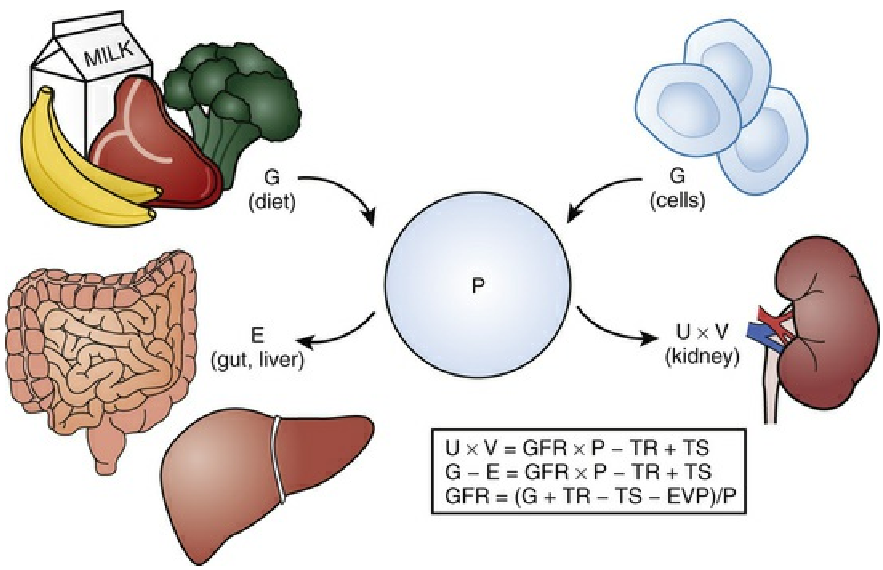

FIG. 74.3 Determinants of the serum level of endogenous filtration markers. The plasma level *(P)* of an endogenous filtration marker is determined by its generation *(G)* from cells and diet, extrarenal elimination *(E)* by gut and liver, and urinary excretion *(U + V)* by the kidney. Urinary excretion is the sum of filtered load *(GFR × P)*, tubular secretion *(TS)*, and reabsorption *(TR)*. In the steady state, urinary excretion equals generation minus extrarenal elimination. By substitution

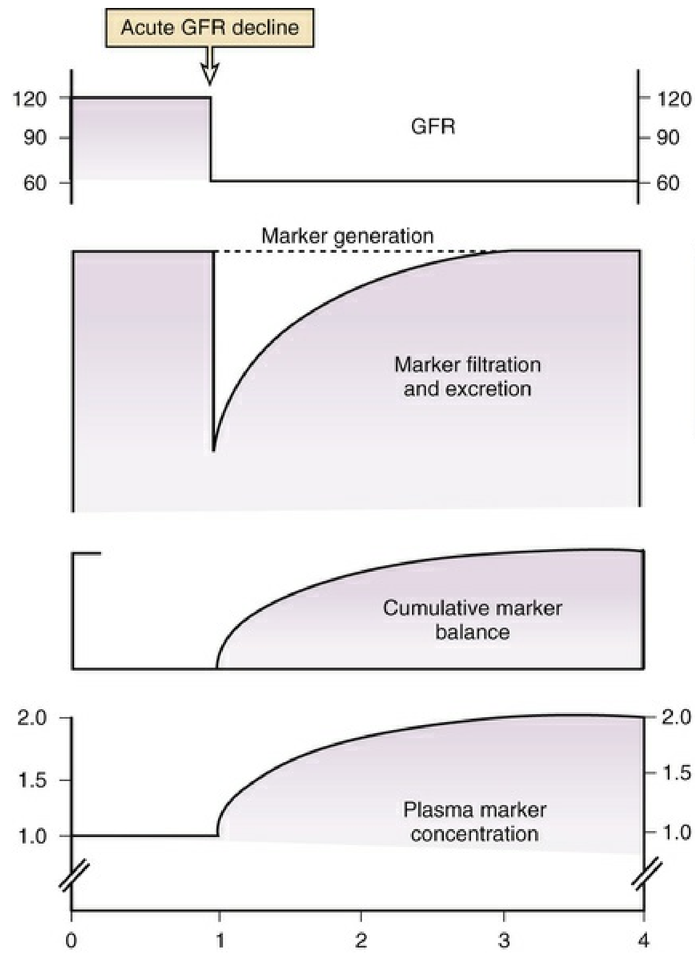
and rearrangement, GFR can be expressed as the ratio of the non-GFR determinants (G, TS, TR, and E) to the plasma level. (Modified from Stevens LA and Levey AS. Measured GFR as a confirmatory test for estimated GFR. J Am Soc Nephrol. 2009;20:2305-2313.)

The second requirement, that excretion of the marker occurs only by glomerular filtration, is also flawed in the case of creatinine. Although the majority of serum creatinine is eliminated by glomerular filtration, a small but unpredictable amount is eliminated by tubular secretion and gastrointestinal degradation. Proximal tubular secretion of creatinine typically accounts for approximately 10% of its elimination, although considerable interindividual and intraindividual variability exist.[55] At normal levels of GFR, the impact of tubular secretion on GFR is minimal. However, with deteriorating renal function, the proportion of secreted versus filtered creatinine increases, resulting in a lower serum creatinine than predicted for the true level of GFR, thus decreasing the sensitivity for serum creatinine to detect mild decreases in renal function.[55] A similar phenomenon occurs in the setting of moderate-to-severe renal failure, when the bacterial degradation of creatinine within the gastrointestinal tract can become clinically significant, leading to a decrease in serum creatinine concentration.[56,57] Failure to recognize the influence of tubular secretion and gastrointestinal elimination on serum creatinine values can result in overestimation of renal function and may lead to higher, inappropriate dosing of medications. Conversely, in patients with advanced kidney failure, administration of medications (eg, cimetidine, trimethoprim) that inhibit the tubular secretion of creatinine or administration of antibiotics that mitigate the gastrointestinal degradation of creatinine may result in an elevation of serum creatinine and subsequent underestimation of GFR without any true change in renal function. If not appreciated, this may be misconstrued as worsening renal function and lead to potential underdosing of medications.

Third, the requirement for a steady state cannot be overemphasized. When GFR abruptly declines with AKI, the production rate of creatinine exceeds its clearance rate leading to a gradual rise in serum creatinine that lags behind the true GFR (Fig. 74.4). During this period, serum creatinine does not accurately reflect the true GFR. Nonetheless, serum creatinine is still typically used to estimate renal function as better alternatives do not currently exist. However, use of the serum creatinine or creatinine-based estimating equations (see later) to estimate GFR before the establishment of a new steady state will result in overestimation of the renal function. Similarly, during the recovery phase of AKI, serum creatinine will underestimate GFR as it will again lag behind the true GFR until the kidney clears the accumulated creatinine and reaches a new steady state.



Day	P_{marker}	eGFR
0	1.0	120
1.5	1.6	79
2.0	1.8	69
2.5	1.9	65
3.0	2.0	60

FIG. 74.4 Following an acute decline in glomerular filtration rate (GFR), filtration and excretion of an endogenous marker (eg, creatinine) decrease while production of the marker remains constant, leading to a gradual rise in serum marker concentration over several days. During this period, use of the serum level of the marker to assess GFR will result in an overestimate, as illustrated earlier (where eGFR is expressed in mL/min/1.73 m^2). The increase in serum marker level results in a higher filtered load until a new steady state is achieved, such that the production and filtration rates of the marker are again equivalent, assuming tubular secretion and extrarenal elimination are negligible. Once a new steady state is achieved, eGFR approaches GFR. (Modified from Stevens LA, Levey AS: Measured GFR as a confirmatory test for estimated GFR. J Am Soc Nephrol. 2009;20:2305-2313; and Kassirer JP. Current concepts: clinical evaluation of kidney function: glomerular function. N Engl J Med. 1971;285:385-389.)

Finally, analytic factors related to the creatinine assay itself provide another potential source of error when assessing GFR. True creatinine levels can be measured by isotope dilution mass spectroscopy (IDMS) or HPLC, but these are expensive and not readily available for routine clinical use.[58] Enzymatic creatinine assays, now available in many laboratories, exhibit greater specificity for creatinine than the conventional Jaffe (alkaline picrate) assay resulting in 10% to 30% lower creatinine levels. Enzymatic creatinine levels approximate high-performance liquid chromatography (HPLC) values but can differ in their performance, some being more influenced by interfering substances than others. Although problems with accuracy and precision still persist, the coefficient of variation using new

autoanalyzers is now approximately 3% and significantly lower than for the Jaffe assay.[51,59] Nonetheless, according to the 2007 College of American Pathologists, many laboratories continue to use a modified version of the Jaffe assay because it is less expensive than enzymatic assays.[60] The Jaffe method, based on an alkaline picrate colorimetric reaction, tends to falsely elevate the true creatinine by up to 20% (for creatinine ~1 mg/dL) due to the presence of interfering, noncreatinine chromagens, the most significant of which is serum total protein.[61] This effect is greatest at the lower levels of creatinine typically observed in infants and children.[62] By falsely elevating the true creatinine, the Jaffe creatinine underestimates the GFR. Indeed, analytic variability is believed to play a greater role than biological variability in the day-to-day fluctuations of creatinine measurements.[51] Speeckaert et al.[61] recently published a correction accounting for the contribution of serum protein to Jaffe creatinines. When applied, this correction yields a creatinine value more consistent with that obtained using an enzymatic creatinine assay. An international effort to standardize creatinine measurements in clinical laboratories through use of a uniform assay and calibration materials was launched in the mid-2000s.[63] All creatinine assays can now be calibrated to adult IFCC (International Federation of Clinical Chemistry) standards. However, the lowest IFCC standard is 1 mg/dL, which is still considerably higher than normal creatinine values for young children and those with decreased muscle mass.[58]

Proper interpretation of the serum creatinine as a measure of GFR, therefore, requires the physician to be knowledgeable about the clinical variables, physiologic processes, and analytic factors that can affect creatinine levels (Table 74.4). Although the clinical laboratory provides normative reference ranges alongside the results, clinicians should confirm that the reported references are age-appropriate and also realize that if the patient has decreased muscle mass (eg, spina bifida, anorexia), even these age-appropriate reference ranges will be incorrect.

TABLE 74.4

Non–Glomerular Filtration Rate Factors Affecting Creatinine Levels in Children

Factor	Serum Creatinine Level	
	Increase	**Decrease**
Affecting creatinine generation	Age (infancy through adolescence)	Chronic illness; anorexia, malnutrition; neuromuscular disease (spina bifida, muscular dystrophy); liver disease
	Male gender (after puberty)	Body habitus (amputation)
	Body habitus (muscular)	Diet (vegetarian)
	Diet; consumption of cooked meat; creatine supplements	
Affecting creatinine elimination	Impaired tubular secretion (trimethoprim, cimetidine)	Tubular secretion
	Impaired extrarenal elimination (sterilization of gastrointestinal flora by antibiotics)	Extrarenal elimination (gastrointestinal degradation)

Cystatin C

The well-established limitations of serum creatinine highlight the critical need to identify alternative biomarkers of renal function that have improved sensitivity and specificity. Some low-molecular-weight proteins have been considered potential

candidate markers as they are excreted primarily by glomerular filtration and are produced at a relatively constant rate. Several low-molecular-weight proteins have been considered but cystatin C, a 13-kDa cationic cysteine protease inhibitor produced at a constant rate by all nucleated cells, has shown the greatest promise. Like creatinine, it is freely filtered at the glomerulus[64] but, unlike serum creatinine, it is not secreted by the tubules; rather, it is completely reabsorbed and metabolized by the proximal tubule epithelial cells.[65] In most studies, the production of cystatin C is not significantly affected by age, gender, and muscle mass, making it a particularly attractive marker in growing children, subjects with atypical body composition (eg, malnutrition, anorexia, spina bifida, neuromuscular disease), and subjects experiencing rapid changes in muscle mass.[66-68] Furthermore, in young children, the maturational changes associated with serum cystatin C follow those of GFR better than serum creatinine. Serum cystatin C levels are elevated at birth, presumably due to the physiologically lower GFR. However, cystatin C, unlike creatinine, does not equilibrate across the placenta; hence the levels early after birth are more representative of the infant's renal function than are creatinine levels and thus may facilitate the evaluation of renal function in newborns.[69] Concurrent with the GFR increasing after birth, cystatin C levels decline to reach a plateau of 0.8 to 1 mg/dL by approximately 1.5 to 2 years of age.[70] Beyond this age, serum cystatin C levels remain constant (until age 50 years), as does GFR.[66] Serum cystatin C levels may therefore potentially facilitate the recognition of abnormal renal function, as growth is no longer a confounding variable.[68] Furthermore, cystatin C has a shorter half-life than serum creatinine, making it more sensitive to acute and subtle changes in GFR.[71,72]

In a small study of healthy subjects, serum cystatin C demonstrated less interindividual variability (25%) than serum creatinine (93%), suggesting it may be a better marker for detecting the onset of acute renal dysfunction. However, the intraindividual variability greatly exceeded that of serum creatinine, limiting its usefulness to monitor the progression of CKD.[73]

Studies comparing the use of cystatin C to serum creatinine as a diagnostic marker of kidney function have yielded conflicting results. Nonetheless, two meta-analyses including adult and pediatric studies suggest cystatin C is superior or equivalent to serum creatinine as a marker of renal function.[74,75] Specifically, cystatin C may be advantageous in populations with low or atypical muscle mass (eg, spina bifida)[76,77] and mild renal impairment.[78] Changes in serum cystatin C levels may also potentially allow earlier detection of AKI. Herget-Rosenthal[79] found that cystatin C levels rose 1 to 2 days earlier than serum creatinine in critically ill adults with AKI. A meta-analysis in 2011 involving mainly adults concluded that serum cystatin C seems to be a good predictor of AKI.[80] However, more recent studies in children have yielded conflicting results.[81,82] Further investigation regarding the use of cystatin C to predict and define AKI is clearly necessary.

Although promising, cystatin C also has limitations for estimating GFR. Cystatin C levels can be affected by several potentially confounding variables including age, gender, race,[83] obesity,[84] nonrenal elimination,[85] glucocorticoids,[70] and thyroid dysfunction,[70] as well as differences in cystatin C assays.[86] At least two automated immunoassays are available (particle-enhanced turbidimetric immunoassay [PETIA] and particle-enhanced nephelometric immunoassay [PENIA]) but differ by as much as 20% to 30% in reported values.[86] Nephelometry is more sensitive than turbidimetry, particularly when dilute solutions are assayed.[53,87] Standardized

reference materials for cystatin C became available in 2010, following which an international effort to standardize cystatin C measurements has been launched.[88-90] Because cystatin C is completely reabsorbed by the proximal tubular cells, urinary clearance studies are not possible. However, cystatin C has been noted in the urine of patients with glomerular and tubular disease, raising questions about its accuracy in estimating GFR.[91]

Estimating Equations

Empiric formulas (Cockcroft-Gault for adults; Schwartz and Counahan-Barratt for children) were first developed in the 1970s to enhance the physician's ability to estimate GFR (eGFR) and, in particular, to facilitate the recognition of chronic renal impairment.[92-94] This is especially helpful in children for whom the serum creatinine corresponding to normal renal function progressively increases during childhood until adult levels are achieved during adolescence. The equations were developed in CKD populations and based on serum creatinine but incorporate clinical variables such as height, weight, age, and gender as surrogates for muscle mass. However, because they are creatinine based, they are subject to some of the same constraints as use of serum creatinine alone; for example, tubular creatinine secretion and technical issues related to the creatinine assay itself will influence eGFR results. Nonetheless, these equations perform better than serum creatinine alone. Current national guidelines now recommend that estimated GFR (eGFR) be routinely reported alongside the creatinine value using the 2009 CKD-EPI (Chronic Kidney Disease Epidemiology Collaboration) formula for adults and the updated "bedside" Schwartz formula for children. Both formulas were developed using creatinine measurements calibrated to be traceable to an IDMS reference standard.[95] Within the past decade, routine reporting of eGFR has been implemented for adults but has been more challenging to implement for children because the equation is based on height, a parameter not routinely available in the laboratory electronic medical record.[71] According to the College of American Pathologists, as of 2013, 90% of laboratories surveyed were reporting eGFR along with creatinine for adults but less than 10% of laboratories surveyed were reporting eGFR for children.[96]

The ideal GFR estimating equation would be based on a standardized creatinine measurement, applicable across the full spectrum of renal function, and generalizable to a diverse population. In 2009, the CKD-EPI creatinine equation was developed using standardized creatinine measurements in a diverse population of adults with and without renal dysfunction. This was a substantial improvement over the 2006 MDRD (Modification of Diet in Renal Disease) equation, which was developed in adults with moderate CKD (GFR <60 mL/min/1.73 m^2) and therefore systematically underestimated eGFR in patients with normal renal function or mild CKD.[97] Limited studies assessing the application of these adult formulas in children have shown them to be inaccurate.[98-101]

In pediatrics, the Schwartz formula has been most commonly used to predict GFR. The original Schwartz formula was developed in the 1970s and based on a modified Jaffe creatinine, using inulin clearance as the reference standard. GFR is related to serum creatinine, using length as a surrogate for muscle mass and an empiric constant to account for age- and gender-related differences in body composition:

$$\text{eGFR} = k \times L/S_{Cr} \quad \textbf{Eq. 74.3}$$

where *eGFR* is estimated GFR in mL/min/1.73 m^2, *L* is length in cm, S_{Cr} is serum creatinine in mg/dL, and *k* is an empiric constant (ie, 0.45 for term infants through the first year of life, 0.55 for children and adolescent females, and 0.7 for adolescent males).[62,94] The simplicity of the formula makes it convenient and practical for use at the bedside, although knowledge of the patient's height is required. Counahan-Barratt developed a similar formula using ^{51}Cr-EDTA plasma disappearance as the reference standard.[93] This formula, however, uses a single constant with a lower value, attributed to a difference in creatinine assays:

$$\text{eGFR (mL/min/1.73 m}^2) = 0.43 \times L/S_{Cr} \quad \textbf{Eq. 74.4}$$

It is now well recognized that Schwartz's original formula systematically overestimates GFR, most likely due to a change in creatinine methodology over the years from the Jaffe assay to an IDMS referenced enzymatic assay.[45] As noted earlier, enzymatic creatinine levels in infants and children tend to run lower than Jaffe creatinine levels.

In 2009 using data from the CKiD Study (Chronic Kidney Disease in Children Study), Schwartz et al. developed an updated “bedside” formula on the basis of an IDMS traceable enzymatic creatinine assay using the plasma disappearance of iohexol as the reference standard:

$$\text{eGFR} = 0.413 \times L/S_{Cr} \quad \textbf{Eq. 74.5}$$

where length is in centimeters and serum creatinine is in mg/dL.[52] Notably, this is the first multicenter study to generate an estimating formula in children with moderate CKD (GFR range 15–75 mL/min/1.73 m^2). Using the updated Schwartz formula, approximately 80% of eGFR values fell within 30% of the GFR measured by iohexol plasma disappearance and 37% fell within 10%.[71] However, similar to the situation with the MDRD equation developed in adults with CKD, the accuracy of the updated bedside Schwartz equation in predicting eGFR for children with mild CKD or normal renal function is unclear.[52] In a cohort of children who had measured GFRs by inulin ranging from 17 to 150 mL/min/1.73 m^2, Gao et al.[102] found the Schwartz formula performed well within the GFR range (15–103 mL/min/1.73 m^2) but overestimated GFR at higher levels of measured GFR. Staples et al.[103] compared the updated Schwartz formula with GFRs measured by iothalamate in a broad pediatric range and found good agreement, even at higher levels of GFR. Other investigators have found the updated Schwartz formula does not perform as well when renal function is normal, but the direction of bias varied by study.[101,103,104]

Other pediatric estimating formulas have been proposed in the past decade.[105,106] Some are considerably more complex, not more accurate, and not easily used at the bedside.[105,106] Pottel's group[107] recently developed an estimating equation for children on the basis of a population normalized serum creatinine value Q (average creatinine for healthy children of a specific age) generated from a large Belgian hospital database:

$$eGFR = 107.3/(S_{Cr}/Q) \qquad \textbf{Eq. 74.6}$$

Using the concept of a population normalized serum creatinine, they developed and validated two new eGFR equations for use in children, adolescents, and young adults.[108] In one, Q is based on height (Q_{height}), whereas in the other, Q is height independent and based on age and gender (Q_{age}). Though both equations have been validated in a Belgian cohort, the Q_{height}-based equation was more accurate across all ages and levels of renal function; it also performed better in underweight subjects, further supporting the premise that height can be used as a good surrogate for muscle mass. The height-independent Q_{age}-based equation, however, may potentially allow development of a screening tool for renal dysfunction in children.[54] Further studies are necessary to assess the applicability of this formula and validity of the technique in other pediatric populations.

Given the limitations of creatinine, cystatin C–based GFR-estimating equations have also been developed in an effort to improve accuracy. Several have been published for use in both adults and children.[90,97,105,109] They vary in accuracy and precision but appear at least as good as the creatinine-based equation[97] for the general population. In high-risk populations with reduced muscle mass such as oncology patients, hematopoietic stem cell transplant recipients, spina bifida/muscular dystrophy, and spinal cord injury patients, cystatin C–based formulas seem to more accurately estimate the measured GFR than creatinine-based equations.[76,110-113] However, cystatin C is not readily available in many hospital laboratories, it is more expensive, and assays have not been standardized in the United States.[70] Incorporation of both creatinine and cystatin C into the estimating formula appears to provide a better estimate than either one alone.[54,97] Using data from the CKiD study, Schwartz et al.[53] developed a new multivariate eGFR equation incorporating both cystatin C and serum creatinine in addition to height, BUN, and gender:

$$\begin{aligned} eGFR = {} & 39.8 \times [\text{height (m)}/S_{Cr}\ (\text{mg/dL})]^{0.456} \\ & \times [1.8/\text{cystatin C (mg/dL)}]^{0.418} \times [30/\text{BUN (mg/dL)}]^{0.079} \\ & \times [1.076]^{gender} \times [\text{height (m)}/1.4]^{0.179} \end{aligned} \qquad \textbf{Eq. 74.7}$$

where *gender* = 1 for male and 0 for female. Using this formula, over 90% of the eGFRs were within 30% of the GFR measured by iohexol, the reference standard for this study, and 48% were within 10%.[52,53] The equation is valid in the range of 15 to 75 mL/min/1.73 m^2 and uses a standardized creatinine measurement and nephelometric assay for cystatin C.[53] The cystatin C values have not yet been referenced to an IFCC calibration. A bedside cystatin C formula has also been generated, $eGFR = 70.69 \times [\text{cystatin C}]^{-0.931}$, to facilitate use in the clinical setting.[53]

Summary of Recommendations Regarding Use of GFR Estimating Equations

Serum creatinine alone does not reliably indicate renal function and should be

replaced by a GFR prediction formula, as this accounts for the non-GFR determinants of serum creatinine. For adults, KDIGO recommends the 2009 CKD-EPI creatinine-based equation be used to routinely assess renal function. For individuals in whom the creatinine-based equation may be inaccurate (eg, malnourished patient), cystatin C and combined cystatin C–creatinine-based estimates are recommended as confirmatory tests. For children, KDIGO recommends use of the updated bedside Schwartz formula (creatinine based). For those in whom a more precise estimate is needed or in whom the use of a creatinine-based formula may be inaccurate, Grubb and CKiD et al.[54] suggest confirmation with a cystatin C–based formula. If the two estimates are similar (within 10%-15% agreement), use of the more complex multivariate cystatin C–creatinine formula provides an estimated GFR, which approximates the measured GFR. If, however, the univariate creatinine-based and cystatin C–based eGFRs are discrepant, a measured GFR is recommended.

Proper use of a GFR estimating formula requires the clinician to be cognizant of the population from which it was derived and its range of measured GFR, as well as the analytes and assay methods used. Finally, it should be reemphasized that none of the GFR estimating equations is truly appropriate for assessing renal function in the non–steady state such as AKI. However, a more suitable alternative does not exist leading to their ongoing use in nonsteady state situations where the imprecision will be even greater.

Neonatal Renal Function

Accurate assessment of renal function is even more challenging in the neonate. Renal clearance and plasma disappearance studies are not practical. The limitations to the interpretation of serum creatinine discussed earlier are further confounded by the unique physiology of newborns. As noted previously, due to maternal-fetal equilibration of creatinine across the placenta, serum creatinine at birth reflects the mother's renal function. For full-term infants, serum creatinine begins falling after birth as GFR increases, resulting in excretion of the maternal load of creatinine. Serum creatinine becomes reflective of the full-term infant's renal function by approximately 1 week of age. On the other hand, premature infants born before the completion of nephrogenesis at 36 weeks gestation have significantly lower GFR at birth than full-term infants and experience a slower maturational increase in GFR, which can result in an initial rise in serum creatinine during the first few days of life.[114] Serum creatinine thus takes longer to become reflective of the preterm infant's renal function. Use of a creatinine-based definition for AKI therefore becomes especially challenging in neonates as renal dysfunction may manifest not only as the traditional rise in serum creatinine but also as a failure for the creatinine to decline at an appropriate rate. Additionally, there are methodologic issues as Jaffe creatinines are less accurate at lower concentrations typical for a neonate.

In this regard, cystatin C may hold more promise as a marker of neonatal renal function. Cystatin C is not thought to equilibrate across the placenta and is therefore considered more reflective of the neonate's renal function from birth.[115] Similar to creatinine, serum cystatin C levels are high at birth but presumably due to a physiologically lower GFR. Levels gradually decline over the next 18 to 24 months to reach a plateau ~0.8 to 1 mg/dL. Reference values for neonatal cystatin C levels are

now available for full-term and preterm infants, but studies are limited and small and do not fully document the normal postnatal course.[116,117]

Given the challenges associated with developing estimating equations in neonates, Abitbol et al.[118] sought to validate existing pediatric GFR estimating formulas in the neonatal population making use of historical controls with GFR measured by inulin clearance. Creatinine-based pediatric equations underestimated GFR when applied to neonates, whereas cystatin C–based and the Zappitelli combined cystatin C–creatinine-based equations correlated best with the measured GFR. Treiber et al.[119] recently developed a neonatal cystatin C–based eGFR equation, which incorporates body surface area and kidney volume as measured by renal ultrasound. They also used historic reference values to validate their equation. Additional research in the field of neonatal renal function and AKI is clearly needed.

Other Novel Biomarkers of Acute Kidney Injury Under Investigation

The currently available tools for assessing AKI are inadequate for detecting the onset of renal cellular damage, as well as the onset of renal functional impairment. Advances in molecular biology have significantly enhanced our understanding of the pathogenesis of AKI, leading to the identification of several potential candidate biomarkers for AKI. NGAL is the most extensively studied and one of the most promising.[120] NGAL is a ubiquitous 25-kDa protein bound to gelatinase from human neutrophils and constitutively expressed at low levels in the kidneys, as well as lung, liver, and gastrointestinal tract.[121] Following ischemia and epithelial cell injury such as after cardiac bypass, NGAL expression is upregulated, leading to marked increases in serum and urine NGAL levels that precede a rise in serum creatinine.[122,123] In a heterogeneous group of critically ill children and adults for whom the onset of renal injury is unknown, Zappitelli et al.[124] found that urine NGAL concentrations increased 48 hours before a serum creatinine increase of 50% or more. They also found that sepsis-related AKI was associated with higher urinary NGAL levels than AKI unrelated to sepsis, a finding also confirmed in adults.[125] Urinary NGAL may thus have variable specificity for predicting AKI on the basis of subtype of AKI. Despite this variability, a meta-analysis including adult and pediatric studies concluded that NGAL levels appear to have diagnostic value.[126]

The expression of kidney injury molecule-1 (KIM-1), a transmembrane receptor with unclear function, also appears to be significantly upregulated in proximal tubular cells following ischemic or nephrotoxic injury. After undergoing cleavage, the extracellular domain is shed into the urine, where it can be detected approximately 12 to 24 hours following the injury. Urinary interleukin-18 (IL-18), a proinflammatory cytokine induced in proximal tubular cells following AKI, appears to be more specific to ischemic AKI and other types of acute tubular necrosis than to other forms of acute renal disease (eg, urinary tract infection or prerenal azotemia).[127] Liver-type fatty acid binding protein (L-FABP), another promising new biomarker expressed in several organs including the liver and kidney, is involved with fatty acid metabolism and intracellular signal transduction; it may also play a role in both kidney injury and repair. Expression within the kidney occurs in both normal and disease states. Urine levels of L-FABP have been reported to increase significantly

within 6 hours after cardiac surgery in children and adults who subsequently developed AKI by serum creatinine criteria.[128] Significant increases have also been noted in patients developing contrast-induced nephropathy.[128]

The role of biomarkers for diagnosing AKI remains in the preclinical/research stages. It is a promising field as use of novel biomarkers offers the potential to localize the site of injury within the kidney (glomerular vs. tubular), as well as the potential to differentiate subtypes of AKI. Indeed, the use of biomarkers in addition to serum creatinine, the traditional marker for AKI, may lead to a new paradigm for AKI: (1) hemodynamic AKI associated with a decrease in GFR but no structural changes within the kidney, (2) subclinical AKI associated with structural injury to the kidney without any apparent loss of function, and (3) AKI in which structural injury to the kidney is associated with a loss of function[129] (Fig. 74.5).

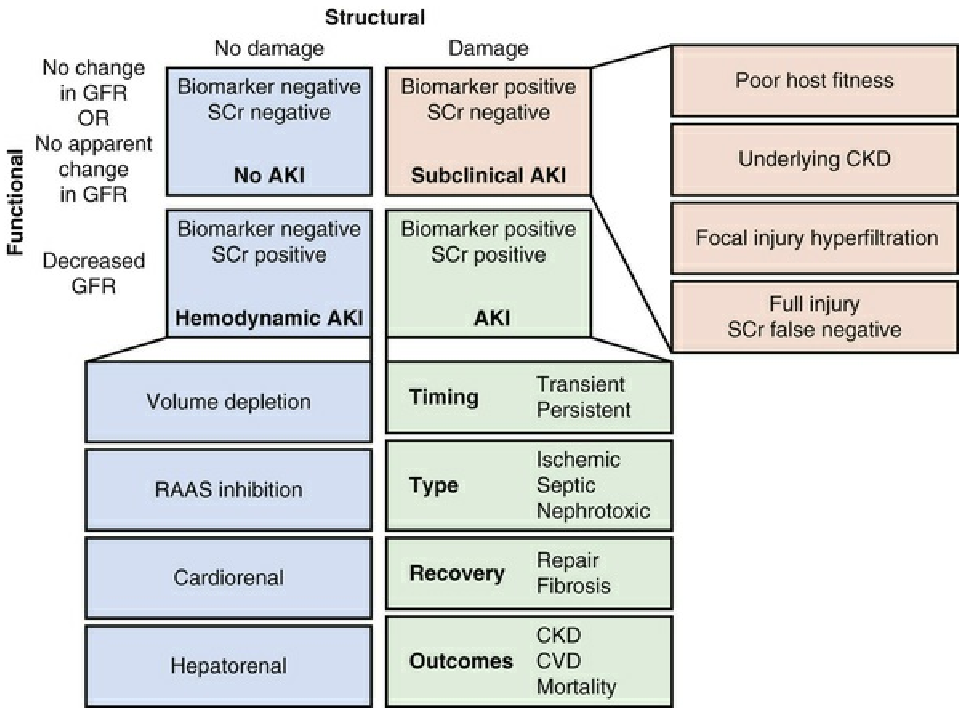


FIG. 74.5 Phenotyping acute kidney injury (AKI) by biomarkers. Identification of clinically relevant structural kidney damage using biomarkers. Concurrent use of intrinsic kidney injury biomarkers and serum creatinine-based estimation of glomerular filtration rate (GFR) identifies at least four clinically relevant categories differentiating prerenal declines in GFR without structural injury and structural injury by biomarker positivity with and without changes in serum creatinine. Establishing AKI biomarker signatures that can further refine and subtype AKI on multiple dimensions has the potential to better identify treatment targets and therapeutic windows. *CKD*, chronic kidney disease; *CVD*, cardiovascular disease; *RAAS*, renin angiotensin-aldosterone system; S_{Cr}, serum creatinine. (Reprinted with permission from Huen SC and Parikh CR. Molecular phenotyping of clinical AKI with novel urinary biomarkers. Am J Physiol Renal Physiol. 2015;309:F408.)

Tubular Function

Disorders of electrolyte balance, acid-base homeostasis, and volume regulation are also encountered in the ICU and require assessment of renal tubular function. Although the techniques required to assess tubular function may be easier to perform than techniques needed to assess GFR, the interpretation of test results is not always straightforward. Whereas a result may fall within the usual limits reported by the laboratory, this may not represent an appropriate response given the clinical context.

Urine Electrolytes (Sodium and Chloride)

Urine sodium (U_{Na}) and chloride (U_{Cl}) are commonly used to assess intravascular volume status and to help differentiate prerenal azotemia from acute tubular necrosis (ATN). With prerenal azotemia, U_{Na} is typically less than 20 mEq/L and U_{Cl} less than 15 mEq/L as the kidney avidly tries to reclaim sodium, chloride, and water in an effort to restore the extracellular fluid volume, whereas with ATN, the U_{Na} is typically greater than 40 mEq/L due to structural tubular damage. However, overlap can occur as the final concentration of sodium in the urine will depend on not only the amount of sodium reclaimed by the tubules but also the amount of water reabsorbed in the distal tubule under the influence of antidiuretic hormone. Thus the U_{Na} could exceed 20 mEq/L even in a prerenal state, particularly if oliguria is present. The fractional excretion of sodium (FE_{Na}) accounts for this differential degree of water reabsorption and therefore provides a more accurate reflection of the kidney's ability to conserve sodium. FE_{Na} represents the fraction of filtered sodium that is excreted into the urine:

$$FE_{Na} = (U_{Na}/S_{Na})/(U_{Cr}/S_{Cr}) \times 100 \qquad \textbf{Eq. 74.8}$$

where U_{Na} and S_{Na} correspond to the urine and serum sodium (mmol/L), respectively, and U_{Cr} and S_{Cr} (mg/dL) correspond to the urine and serum creatinine, respectively. With prerenal azotemia, the FE_{Na} is generally less than 1%, whereas with ATN it is greater than 1%. In premature infants, due to tubular immaturity, this threshold for FE_{Na} is approximately 3%, not 1%. It should be noted that FE_{Na} is really only meaningful in the setting of oliguric AKI. In euvolemic patients, the urinary excretion of sodium will be more dependent on dietary sodium intake. The accuracy of U_{Na} and FE_{Na} is further compromised when urinary salt-wasting conditions are present (eg, diuretic use, renal dysplasia, chronic renal failure, cerebral salt wasting, as well as mineralocorticoid deficiency such as congenital adrenal hyperplasia secondary to 21-hydroxylase deficiency). These conditions are associated with elevated urinary chloride levels as well.[130]

Urine Concentration Capacity

The urine specific gravity (U_{SG}) and urine osmolality (U_{Osm}) assess the kidney's ability to concentrate the urine. U_{SG} and U_{Osm} bear a linear relationship, with U_{SG} rising approximately 0.001 for every 30 to 40 mOsm/kg. When urine is iso-osmotic to

serum, the U_{SG} is approximately 1.010. In a healthy kidney, the limits of U_{SG} range from 1.003 to 1.035 and U_{Osm} from 50 to 1400 mOsm/kg. However, due to renal immaturity, infants have a reduced urinary concentration capacity of about 600 mOsm/kg for preterm and 800 mOsm/kg for full-term infants. U_{SG} can be easily measured by refractometer and is therefore clinically used more often than U_{Osm}, which requires an osmometer. In general, U_{SG} provides a good estimate of the kidney's concentration ability. However, because U_{SG} compares the density of urine to that of water, the presence of heavier solutes such as glucose, contrast dye, or protein can increase the urine specific gravity without affecting the urine osmolality. Urine osmolality therefore provides a more accurate assessment of the kidney's response to antidiuretic hormone (ADH). With prerenal azotemia, the appropriate renal response is to retain sodium and water. Classically, the U_{SG} exceeds 1.020, U_{Osm} exceeds 500, and the urine output decreases, with the patient often becoming oliguric (urine output <1 mL/kg/h). With ATN, on the other hand, the conservation of water is impaired secondary to tubular injury resulting in isosthenuria (U_{SG} ~1.010, U_{Osm} ~300–350 mOsm/kg). It is crucial to remember, however, that children with underlying urinary concentration defects and tubular resistance to ADH (eg, renal dysplasia, nephrogenic diabetes insipidus, chronic kidney failure) may have a low U_{SG}, low U_{Osm}, and high urine output despite life-threatening intravascular volume depletion.

Urine osmolality is also helpful in evaluation of the child with polyuria. A low osmolality (<150 mOsm/kg) suggests a urinary concentration defect such as central or nephrogenic diabetes insipidus, whereas a urine osmolality of 300 to 350, associated with a high specific gravity, suggests an osmotic diuresis. The urinary concentrating capacity can be assessed by (1) checking the osmolality of a first morning urine after overnight fluid restriction with close monitoring or (2) a water deprivation test.

Serum Blood Urea Nitrogen/Creatinine Ratio

The ratio of serum blood urea nitrogen (BUN) to creatinine is also frequently used to help differentiate prerenal AKI from ATN. Urea, like creatinine, is freely filtered at the glomerulus but, unlike creatinine, has significant tubular reabsorption that further increases with hypovolemia. In prerenal states, therefore, the BUN/creatinine ratio generally exceeds 20 : 1, while it is lower than this with ATN. However, this ratio becomes inaccurate in clinical conditions where the BUN is elevated for nonrenal reasons such as a gastrointestinal bleed, catabolic state, or corticosteroid use; nor is it accurate in clinical conditions associated with a low BUN, such as protein calorie malnutrition or liver disease. The ratio may also be misleading in conditions associated with a particularly low muscle mass and serum creatinine such as muscular dystrophy.

Urine Microscopy

Urine microscopy can aid in determining the etiology for AKI. The presence of muddy brown or renal cellular casts and renal tubular epithelial cells is consistent with ATN. However, the absence of such findings does not rule out less severe ATN.

In the setting of prerenal azotemia, urine microscopy is bland; hyaline and granular casts may be seen. Hematuria with dysmorphic red blood cells (RBCs) and red cell casts is consistent with glomerulonephritis, whereas hematuria with eumorphic RBCs suggests lower tract bleeding and hematuria in the absence of RBCs on a freshly examined urine suggests hemoglobinuria or myoglobinuria. Leukocyturia with white cell casts suggests pyelonephritis or interstitial nephritis. Eosinophils in the urine can be detected using special stains and are classically associated with interstitial nephritis but can also be seen with pyelonephritis and urinary tract obstruction.[131] Examination of a fresh, concentrated (or first morning) urine specimen optimizes the opportunity for detecting these cellular elements.

Proteinuria

Protein excretion in healthy individuals is minimal (<4 mg/m^2/hour in children) but can increase with renal injury. Glomerulopathies are associated with albuminuria and nonspecific proteinuria, while tubulointerstitial disease results in low-molecular-weight proteinuria (eg, β_2-microglobulin, retinol binding protein).

Urinary protein excretion can be detected qualitatively by reagent strips. However, these strips only detect albumin and are therefore helpful for assessing glomerular proteinuria but not tubular or low-molecular-weight proteinuria. Low-level proteinuria by dipstick (30–99 mg/dL) can be a false positive in alkaline urine or can signify more significant disease if the patient is polyuric. Quantitative assessments of proteinuria can be obtained using a random urine total protein/creatinine ratio (normal <0.2 for children older than 3 years) measured by the biuret method[132] and are preferred for following glomerular and tubular proteinuria. First morning urine specimens are often recommended as this can distinguish orthostatic proteinuria, which is benign, from fixed proteinuria, which is pathologic. Twenty-four-hour urine collections for protein and creatinine can also be performed but are not believed to be advantageous over the random urine protein/creatinine ratio, particularly in children.

In diabetics, the development of overt proteinuria detectable by reagent strips is preceded by the presence of microalbuminuria, defined as persistent albumin excretion between 30 and 300 mg/g creatinine.[133] Use of the microalbumin/creatinine ratio allows for early detection of glomerular damage in diabetic kidney disease.[25]

Renal Acidification

Metabolic acidosis is also commonly encountered in the PICU. When associated with a normal serum anion gap, the major diagnostic consideration is renal tubular acidosis versus gastrointestinal loss of bicarbonate. The appropriate renal response to a metabolic acidosis is to increase proton secretion and ammonium production, which will allow increased net acid excretion (also see Chapter 76). The urine pH in this case should fall below 5.3, ideally measured with a pH meter after collecting a fresh specimen in an airtight syringe. Whereas a urine pH greater than 5.3 in the setting of systemic acidemia is consistent with renal tubular acidosis, a urine pH less than 5.3 does not exclude the diagnosis. Proximal RTA is characterized by bicarbonaturia secondary to a reduced threshold for bicarbonate reabsorption. At low levels of serum bicarbonate (<14 mEq/L), the filtered bicarbonate is able to be

reabsorbed, resulting in a low urine pH. However, under conditions of bicarbonate loading, the reabsorptive capacity of the proximal tubule is exceeded leading to fractional excretion of bicarbonate greater than 15% to 20%:

$$FE_{bicarb} = (U_{HCO3}/S_{HCO3})/(U_{Cr}/S_{Cr}) \times 100 \qquad \textbf{Eq. 74.9}$$

where U_{HCO3} and S_{HCO3} are the urine and serum bicarbonate concentrations in mmol/L and U_{Cr} and S_{Cr} are the urine and serum creatinine concentrations in mg/dL. Assessment of distal acidification includes calculation of the urine net charge and osmolal gap, both of which provide an indirect assessment of ammonium production, which cannot be routinely measured. The former is simpler to calculate:

$$\text{Urine Net Charge} = (U_{Na} + U_K - U_{Cl}) \qquad \textbf{Eq. 74.10}$$

where U_{Na} is the urine sodium concentration (mEq/L), U_K is the urine potassium concentration (mEq/L), and U_{Cl} is the urine chloride concentration (mEq/L). Assuming chloride is the major anion excreted, an appropriate urine net charge in the setting of acidosis should be negative (−30 to −50), indicating the presence of ammonium, an unmeasured cation. A positive net charge would therefore suggest impaired ammonium production or proton secretion. The urine net charge, however, has limited utility when the urine sodium concentration is low (<25 mEq/L), as occurs with hypovolemia. In this setting, the kidney avidly conserves sodium and chloride (urine chloride <15 mEq/L), leaving less anion available for excretion with ammonium and resulting in a reversible impairment of urinary acidification. The urine net charge is also misleading in the presence of unmeasured anions (eg, beta hydroxybutyrate and acetoacetate in diabetic ketoacidosis, hippurate from toluene ingestion/glue sniffing, or penicillins). In this setting, the urine net charge is positive and underestimates ammonium excretion because the cations—ammonium, sodium, and potassium—are excreted with the unmeasured anion instead of chloride. In infants, the validity of the urine net charge is also compromised due to considerable variability in the unmeasured ionic composition of the urine.[134] The urinary osmolal gap is more informative because it accounts for the excretion of the unmeasured anions. It represents the difference between the measured and calculated urine osmolalities where the calculated osmolality is:

$$\begin{aligned} U_{Osm} = {} & \{2 \times [U_{Na}\ (\text{mmol/L}) + U_K\ (\text{mmol/L})]\} \\ & + [U_{urea}\ (\text{mg/dL})/2.8] + [U_{glucose}\ (\text{mg/dL})/18]^{135} \end{aligned} \qquad \textbf{Eq. 74.11}$$

Assuming urinary ammonium is the predominant unmeasured cation, the concentration of excreted ammonium is approximately half of the urine osmolal gap. During periods of systemic acidosis, urinary ammonium excretion increases to concentrations greater than 75 mEq/L; a level less than 25 mEq/L in this setting suggests impaired ammoniagenesis.[136]

More sophisticated tests are available to assess distal tubular acidification (proton

secretion). Traditional tests include (1) measuring the difference in PCO_2 between the urine and blood during bicarbonate loading and (2) an NH_4Cl loading test. However, these can be difficult to perform and may not be well tolerated. More recently, simultaneous administration of furosemide to enhance distal sodium delivery and fludrocortisone to enhance distal sodium reabsorption, as well as stimulate proton secretion, has been used as an alternative test for distal acidification. In the presence of intact distal acidification, the urine pH should decrease to less than 5.3. This test has the advantages of being easy to perform and well tolerated.[137]

Potassium Regulation

Unlike urine sodium, which can be extremely efficiently reclaimed by the tubules, there is an obligate K excretion of at least 5 to 10 mmol/day due to K secretion that occurs in the distal tubule. Potassium excretion is primarily dependent on the aldosterone activity and serum K concentration but also requires an adequate urine flow rate and delivery of sodium to the distal nephron. The TTKG (transtubular potassium gradient) provides an assessment of potassium excretion secondary to mineralocorticoid activity and is calculated:

$$\mathrm{TTKG} = [\mathrm{U_K} \times \mathrm{S_{Osm}}]/[\mathrm{S_K} \times \mathrm{U_{Osm}}] \qquad \textbf{Eq. 74.12}$$

where U_K and S_K represent urine and serum concentrations of potassium (mEq/L), respectively, and S_{Osm} and U_{Osm} represent serum and urine osmolalities (mOsm/kg). In the setting of hyperkalemia, the TTKG should be elevated; therefore a low TTKG (<4.1 in children; <7 in adults) suggests hypoaldosteronism. In the setting of hypokalemia, on the other hand, the TTKG would be expected to be quite low; levels greater than 2 suggest aldosterone activity is not appropriately suppressed.[130,138]

Generalized Proximal Tubulopathy

Generalized proximal tubulopathies (Fanconi syndrome) can be congenital (ie, cystinosis, tyrosinemia) or acquired (eg, aminoglycoside toxicity, ifosfamide, severe ATN) and may be partial or complete. Biochemical abnormalities associated with a complete Fanconi syndrome include hypokalemia, metabolic acidosis, hypophosphatemia, hypouricemia, and low serum carnitine associated with urinary wasting of sodium, potassium, bicarbonate, phosphorus, uric acid, carnitine, glucose, amino acids, and low-molecular-weight proteins. A generalized proximal tubulopathy should be suspected when electrolyte wasting is profound and/or involves several electrolytes.

CHAPTER 75

Glomerulotubular Dysfunction and Acute Kidney Injury

Cristin D.W. Kaspar, Timothy E. Bunchman

PEARLS

- Acute kidney injury (AKI) has replaced the term *acute kidney failure*. There are more than 30 definitions of AKI in children. Use of the pediatric Risk, Injury, Failure, Loss, End stage renal disease (pRIFLE), Acute Kidney Injury Network (AKIN), or Kidney Disease Improving Global Outcomes (KDIGO) scores for AKI may help in streamlining the definition. In the future, biomarkers may add clarity to this definition at an earlier time frame than when they are presently used.
- In the critically ill child, AKI is often associated with cardiovascular instability, which, if prolonged, exhausts the normal kidney compensatory responses to maintain kidney blood flow and glomerular filtration.
- Because tubular blood flow, and thus oxygen delivery to this vital epithelium, depends on postglomerular blood flow, prolonged vasoconstriction of glomerular arterioles results in tubular necrosis.
- Nephrotoxic drugs, sepsis, and overzealous use of diuretics are common comorbid conditions that further contribute to AKI.
- Attention to cardiovascular status and the avoidance of unnecessary nephrotoxic agents such as aminoglycosides, nonsteroidal antiinflammatory drugs, and contrast agents may avoid further AKI.

Acute kidney injury (AKI) is a frequent problem in the pediatric intensive care unit (PICU), but an accurate incidence is difficult to establish due to the ongoing evolution of a clear definition of renal failure. The classic definition was a 50% reduction of glomerular filtration rate (GFR) accompanied by a 50% increase in creatinine. A RIFLE classification of renal injury to allow earlier appreciation of renal dysfunction is now utilized in adults and a modification of this system (pRIFLE) can

also be applied to children.[1-3] However, use of serum creatinine level in the diagnostic criteria is problematic for several reasons including variability of creatinine based on muscle mass and a delay in the rise of creatinine after kidney injury.

Early detection of renal dysfunction by biomarkers is needed to allow a more timely awareness of injury and thereby allow modifications to alleviate the renal stress. Investigations in this area, although early in their development, postulate that a panel approach (plasma panel of neutrophil gelatinase-associated lipocalin [NGAL] and cystatin C or a urine panel of NGAL, interleukin 18, and kidney injury molecule-1 [KIM-1]) may be of help in the future to provide more sensitive and specific detection of early AKI.[4-6]

Acute Kidney Injury Pathophysiology

Physiology of Glomerular Filtration

GFR is the product of the filtration rate of the individual nephron and the number of functioning nephrons.[7] A single nephron glomerular filtration rate (SNGFR) is defined by the Starling forces of the glomerular capillaries and the properties of the glomerular capillary wall,

$$SNGFR = Kf\,(\Delta P - \Delta \pi) = KfP_{uf} \qquad \textbf{Eq. 75.1}$$

where *Kf* is a capillary wall property known as the ultrafiltration coefficient and is the product of the surface area available for filtration and the hydraulic conductivity of the membrane. The Starling forces (or pressures) that affect filtration are the hydraulic pressure in the glomerular capillary (P_{gc}), the hydraulic pressure in the Bowman space (P_{bs}), the oncotic pressure of the glomerular capillary (π_{gc}), and the oncotic pressure in the Bowman space (π_{bs}), which is usually zero because the ultrafiltrate is essentially protein free.[8] P_{gc} favors filtration; P_{bs} and π_{gc} are opposing forces to filtration. The mean ultrafiltration pressure (P_{uf}) is the difference between the net change in hydraulic pressure and the net change in the oncotic pressure. Thus SNGFR may be modified by alterations in the glomerular capillary pressures, glomerular membrane characteristics, or the surface area available for filtration.

The kidneys are responsible for plasma water and electrolyte balance through filtration at the glomerular membrane and then reabsorption of this filtrate from the renal tubular epithelium. The loss of filtration and tubular reabsorption in AKI is the result of renal adaptive changes that initially function to preserve renal perfusion and glomerular filtration; however, when these are exhausted, the kidney's compensatory mechanisms fail and renal dysfunction ensues.

Glomerular filtration depends on adequate renal perfusion; the kidneys receive approximately 25% of total cardiac output. The fraction of cardiac output perfusing the kidneys is related to the ratio of renal vascular resistance (RVR) and systemic vascular resistance.[9] Renal blood flow (RBF) is determined by systemic blood pressure (SBP) and RVR, expressed by the formula RBF = SBP/RVR.[9] Kidney autoregulation, which maintains a constant renal perfusion pressure, occurs through

alterations in RVR in response to changes in systemic vascular resistance or intravascular volume. When SBP is within the normal physiologic or autoregulatory range, the kidney can maintain constant blood flow and GFR by dilation of the preglomerular or afferent arteriole, which reduces RVR and increases RBF. This afferent arteriole dilation is accomplished by two known mechanisms, smooth muscle relaxation of the afferent arteriole in response to sensing a transmural pressure drop (the myogenic reflex[3]) and the tubuloglomerular feedback system. The tubuloglomerular feedback system is operational following a reduction of plasma flow. When solute and water deliveries to the macula densa are reduced, the juxtaglomerular apparatus responds by relaxing the smooth muscle of the adjacent afferent arteriole. Thus a reduction in cardiac output or effective renal plasma flow is accompanied by vasodilation at the preglomerular arteriole, which in turn reduces RVR, thereby restoring RBF.

During states of reduced cardiac output or intravascular volume depletion, the systemic vasoconstrictors, angiotensin II and vasopressin, are released to help preserve vascular tone. The kidney counteracts the renal vasoconstrictor activity of angiotensin II and increased sympathetic tone through the intrarenal production of vasodilatory prostaglandins such as prostaglandin I_2.[10] These locally produced substances may attenuate renal vasoconstrictive forces and help preserve renal perfusion. Animal model data of congestive heart failure have provided evidence that enhanced prostaglandin synthesis is required for preservation of renal perfusion and GFR. Patients receiving prostaglandin synthetase inhibitors such as nonsteroidal antiinflammatory drugs (NSAIDs) have potentiation of renal ischemia because of an increase in renal vasoconstriction not antagonized by intrarenal prostaglandin synthesis.[11] Endothelium-derived relaxation factors (EDRFs), which are vasodilatory, and the potent vasoconstrictor endothelin, produced by the endothelium, may also affect the regional vascular tone.[12]

Constriction of the postglomerular capillary sphincter, the efferent arteriole, in the face of reduced RBF increases the filtration fraction and preserves GFR, although this occurs at the expense of renal plasma flow, which may be further reduced. Vasoconstriction at the efferent arteriole is mediated by angiotensin II and, to a lesser extent, by the action of the adrenergic system by epinephrine.[13] Elevation in postglomerular arteriolar resistance may be blocked by the angiotensin-converting enzyme inhibitors. When converting enzyme inhibitors are administered to the patient who requires efferent arteriolar constriction to maintain GFR, renal decompensation often results.[14]

As previously noted, reductions in effective intravascular volume and cardiac output are accompanied by increased activity of the sympathetic nervous system and the renin-angiotensin-aldosterone system and increased circulating levels of vasopressin (see also Chapter 81).[15] Hormonal and neural systems signal the kidneys to increase the reabsorption of sodium and water to help restore the deficient intravascular volume, increase cardiac output, and consequently improve RBF. These and the kidney's homeostatic mechanism, by afferent arteriolar vasodilation and efferent arteriolar constriction, maintain the kidney's glomerular filtration. The kidney's homeostatic mechanisms, however, are not without limitation. The autoregulatory ability of the afferent arteriole is maximal once the mean SBP falls below 80 mm Hg. The renal autoregulatory range appears to be age dependent, because younger animals can autoregulate over lower pressure ranges. The range of

perfusion pressure over which the kidney can autoregulate may be limited in certain conditions so that vasodilation is maximal with a minor reduction in mean arterial blood pressure. Examples include extracellular fluid depletion, renal ischemia, or renal vascular disease (eg, hypertension, diabetes, atherosclerosis).

As the stimulus for release of vasoconstrictors continues, afferent arteriolar constriction rather than vasodilation may predominate, and the result is a decrease in renal plasma flow and filtration rate.

Constriction of the afferent arteriole may be stimulated by increased sympathetic nervous system activity and increased levels of endogenous or exogenous circulating catecholamines such as dopamine or norepinephrine. Thus the administration of these vasoactive-inotropic agents may actually compromise the kidney's adaptive mechanisms. Excessive vasoconstriction eventually results in diminished filtration rate and oxygen delivery to the kidney.

Pharmacologic agents may alter renal perfusion by changing SBP through an action on systemic vasculature or by direct effects on renal vasculature (Box 75.1). Vasodilators, such as hydralazine, lower SBP without changing renal perfusion pressure because the decrease in SBP is accompanied by decreased RVR. Conversely, epinephrine increases SBP but decreases RBF by its vasoconstrictor effect on intrarenal blood vessels.

Box 75.1

Vasoactive Substances in the Kidney Vasculature

1. ↑ Kidney Vascular Resistance/↓ Kidney Blood Flow

- Epinephrine
- Norepinephrine
- Angiotensin II
- Arachidonic acid
- Thromboxane A_2

2. ↓ Kidney Vascular Resistance/↑ Kidney Blood Flow

- Prostaglandin E_1
- Prostaglandin E_2
- Dopamine
- Furosemide

- Angiotensin-converting enzyme inhibitors
- Bradykinin
- Isoproterenol
- Acetylcholine

Morphologic Changes in Renal Injury

Morphologic changes seen in acute renal injury, especially those in the tubules, depend on the duration of injury as well as the eliciting mechanism.

The kidney's complex structure, with heterogeneous segments within the kidney receiving differential regional perfusion and thereby oxygenation, sets up a common form of renal failure, that of the tubulointerstitium. This region is at greatest risk for ischemia because of its gradient of regional perfusion and oxygenation. In addition, vascular disease, including glomerular disease, often occurs in children and results in AKI, but there are studies that suggest the extent of damage to the tubulointerstitium has the greatest prognostic implication to the degree of final renal recovery.[16]

Initial structural changes in tubular cells are seen as apical and basal surface changes of simplification, with microvilli of the brush border shortening and disappearing by either detachment from the apical surface or being internalized within the tubular cells.[17]

In this scenario, enzymes of the brush border (alkaline phosphatase and gamma glutamyl transpeptidase) may be found in the urine and may be used as markers of early tubular injury.[18] The loss of microvilli surface area leads to loss of enzymes and transport sites for transcellular absorption and apical uptake. Additionally, loss at the basolateral interdigitating infoldings of the tubular cells then results in further reduction of surface area for transport and loss of the Na^+/K^+-adenosine triphosphatase (ATPase) that is localized to this membrane and involved in many transport processes.[19]

Morphologic changes in distal tubules and outer medulla also occur and may be found even when proximal tubular injury is not readily identified on biopsy. Experimentally, the outer medulla has been identified as sensitive to hypoxia, including that induced by toxins such as radiocontrast agents and cyclosporine.[20]

Injury at this outer medulla region may be missed on biopsy since this site often is not sampled. Tubular cell detachment with exposed, denuded regions of the basement membrane can be found on biopsies, as a result of altered cell-matrix attachments.[21]

Renal tubular sensitivity to ischemic injury is primarily influenced by the individual renal cell's energy requirements, its glycolytic capacity, and the extent of hypoxic stress upon the cell. Glycolysis and oxidative phosphorylation both supply the adenosine triphosphate (ATP) required by the cell to drive its metabolism, and it follows that cells with a greater capacity for glycolysis (distal tubular cells) are less sensitive to oxygen deprivation than the cells that rely mainly on mitochondrial-derived energy (proximal tubular cells).[22]

In vivo and in vitro studies may be discordant in identifying susceptibility to hypoxia. Medullary straight portions of the proximal tubule have a higher glycolytic capacity than the cortical segments of the proximal tubule but, due to the regional distribution of perfusion within the kidney, the medullary portions operate in a lower oxygen-tension environment and therefore are more susceptible to hypoxia/ischemic injury.[23] The individual cell's energy requirements to conduct its transport activities further influences its risk to hypoxic injury. The outer medullary proximal tubular cell (pars recta), due to the high energy requirements for its transport functions, has a greater injury risk than the deep inner medullary tubular cell with its low-oxygen and low-energy requirement to maintain its transport function.[24]

When energy stores are rapidly depleted, the normal Na^+/K^+ ATPase pump begins to fail and the most basic of cell function, membrane integrity, is jeopardized, with resultant accumulation of Na^+, Cl^-, and water within the cell; this cell swelling (oncosis) is a hallmark feature of necrosis.[25] Not all cells that fail to maintain their energy requirements die through necrosis. Apoptosis, which appears morphologically as cell shrinkage, is also a result of inadequate energy support. Apoptosis is an asynchronous cell death triggered over hours to days, with the earliest cellular element involving mitochondrial changes including loss of transmembrane potential and release of mitochondrial cytochrome c into the cytosol.[30] It is mitochondrial function/dysfunction that primarily determines the fate of the cell for recovery and survival or death and by what form: apoptosis or necrosis[11] (see also Chapter 84).

Pathogenesis of Reduced Glomerular Filtration Rate in Acute Kidney Injury

The mechanisms responsible for GFR reduction in acute renal injury have been studied extensively with experimental models of AKI. Multiple mechanisms are often operational in mediating hypofiltration. Whereas one factor may have greater importance in the initiation of injury and decreased filtration, others are involved in the sustained reduction in GFR during the maintenance phase of AKI. Four major mechanisms result in reduced GFR during AKI: reduced blood flow, decreased Kf, tubular obstruction, and back leakage of tubular fluid.[31] Each factor is discussed regarding its role in both the initiation and maintenance phases of AKI.

A reduction in RBF can be demonstrated during the initiation phase of many forms of AKI and seems to play a predominant role in ischemic injury and rhabdomyolysis.[31] Proposed theories for the reduction of RBF include (1) a proportional increase in the afferent and efferent arteriolar resistances in response to activation of the renin-angiotensin system, (2) vascular endothelial cell swelling and damage with release of vasoactive peptides such as endothelin, and (3) hyperemic congestion of the medullary peritubular capillaries.

Kf may be reduced in both nephrotoxic and ischemic forms of renal failure. Endothelial or mesangial cell swelling reduces the surface area available for filtration; altered permeability induced by humoral factors such as angiotensin II and vasopressin may also decrease Kf. Circulating levels of both hormones are increased during AKI.

Renal tubular cells are the primary site of injury in both ischemia and

nephrotoxin-induced renal injury. Tubular cell injury may be sublethal or lethal and result in cell necrosis or apoptosis. Once this injury occurs, cells detach from the supporting basement membrane and obstruct the tubule lumen. In addition, even with sublethal injury, tight junctions may be disrupted, and the intact layer may be lost. The loss of epithelial integrity allows back leakage of ultrafiltrate, which contains creatinine and urea, through paracellular pathways into the renal interstitium, creating further diminution of excretory function and reduced urine formation. Necrosis of a selected region of the renal tubule is accompanied by tubular obstruction and eventual filtration failure by that entire unit or nephron.

Intratubular obstruction occurs in most forms of acute renal injury, either as a contributing factor in the initiation phase or during the maintenance phase.[31] Tubular obstruction with cellular debris and precipitated protein is a prominent finding in both the initiation and maintenance phases of ischemic injury. In the case of nephrotoxic injury, the degree of injury may determine the extent of tubular obstruction. In an experimental model of gentamicin nephrotoxicity, the drug dose was positively correlated with the contribution of tubular obstruction to reduced GFR.[31] Tubular obstruction and loss of epithelial integrity caused by tubular cell injury result in the back leakage of tubular fluid and solutes. Excretion of solute and fluid is decreased, and this decrease possibly signals a further reduction in the GFR by stimulation of the tubuloglomerular feedback mechanism.[31] Back leakage of fluid involves tubular factors and is not a result of hypofiltration, although it does impair the excretory function of the kidney. Consequently, a falsely low estimation of actual GFR may occur because tubular fluid containing urea and creatinine leaks back into the vascular space and interstitium. Prevention of the tubular obstruction may alter the course of renal failure, even in those states in which the primary mechanism of injury is not obstruction.

AKI may be viewed as an evolving process into three phases[32]: (1) an initiation phase in which the primary mechanism of injury is operational, (2) a maintenance phase during which renal function remains poor and other factors may contribute to sustained injury, and (3) a recovery phase during which there is regeneration of cells and restoration of function. Although the primary initiating event may be hypoperfusion with ischemia, often it involves multiple contributing factors that mediate additional cellular damage, usually through alterations in energy supply. From a clinical perspective, it may be most helpful to consider acute renal dysfunction syndromes according to the cause of the inciting event; however, it is equally vital to understand the other contributing mechanisms that ultimately affect outcome.

Endothelial injury and vascular dysfunction have been postulated to occur during the initiation and particularly during the maintenance phases of AKI. Although most studies have focused on the tubular cell as the primary site of injury leading to dysfunction, studies have provided insight into the potential role for endothelial injury in continued reduced RBF and altered vascular function.[33] Sutton and colleagues proposed that an additional phase be added to the current model for AKI: After the initiation phase, an extension phase occurs that is due to microvascular injury related to ischemic damage to endothelial cells, infiltration of leukocytes, and activation of the coagulation system. This process is thought to predominate in the corticomedullary and outer medullary microvessels and may occur in the face of early tubular cell regeneration so that limiting the extension process provides a

potential mechanism for aiding recovery.

Mechanisms of Renal Cell Injury

The renal tubular cell expends energy in the form of ATP to maintain a high intracellular concentration of potassium and a low intracellular concentration of sodium. This concentration gradient depends on the continuous activity of the Na^+/K^+-ATPase and is the driving force for the reabsorption of sodium. Active reabsorption of sodium is the primary driving force for water reabsorption and the coupled transport of amino acids, carbohydrates, organic acids, and other compounds. Thus all transport functions, as well as many other vital cell functions, depend on normal activity of the Na^+/K^+ pump, which, in turn, depends on an adequate supply of energy. In addition, membrane fluidity or integrity is important to transport functions in tubular cells. Processes that result in alterations in the membrane or in the supply of energy are common final pathways for renal tubular cell death.

A decrease in the cellular ATP content occurs in many forms of renal injury, possibly as the result of primary alterations in the cell's ability to perform oxidative phosphorylation or as the end result of other perturbations. Heterogeneity exists in the susceptibility of nephron segments to oxygen deprivation with more distal segments being relatively resistant. This is related to the greater glycolytic capacity of the distal tubule compared with the proximal tubule, which relies on oxygen-consuming pathways for ATP generation. Therefore the net result of renal injury is usually a depletion of energy in the form of ATP, with the inability of the cell to perform vital functions, including transport and maintenance of cell integrity.

Cellular injury may be modified by the requirements made on its energy stores. If more transport is required of the cell, more energy is consumed, and less energy is left for cell maintenance. Evidence exists to support this theory. If transport requirements are reduced by the administration of diuretics or by the stimulation of the glomerulotubular feedback mechanism, then further injury may be attenuated. The feedback mechanism, whereby there is reduction of GFR in the face of reduced reabsorption by the proximal tubule, is a protective signal that conserves cell energy by reducing metabolic demands made on the cell.

Heat shock proteins (HSPs) are a family of proteins that appear to protect cells from injury as a result of hyperthermia, ischemia, or toxins. The HSP induction by sublethal thermal stress has been found to attenuate subsequent injury in the kidney.[34] Renal transplants from animals that underwent short-term hyperthermia had better initial function and subsequent survival. Furthermore, in cultured inner medullary collecting-duct cells, induction of HSP-1 by preconditioning hyperthermia attenuated the alterations in mitochondrial function and glycolysis that were observed after cells were exposed to high temperatures. Investigations into potential mechanisms to use this natural cell defense mechanism are under way.

The ability of renal tubular epithelial cells to undergo regeneration determines in large part the degree of renal recovery. Therefore much work has been done to study ways that cells regenerate and mechanisms that might enhance recovery. Early in ischemic injury there is induction of early response genes such as c-fos and Egr-1.[35] By 2 days after ischemia, the proliferating cell nuclear antigen is detected, followed by expression of other dedifferentiated cell markers, which seem to be a sign of early

recovery. Other cells appear to undergo apoptosis or cell death. Postischemic regeneration seems to be a recapitulation of early renal tubular cell development. Growth factors such as insulin-like growth factor-1 (IGF-1) and epidermal growth factor 1 (EGF-1) have been associated with enhanced recovery as well. Renal levels of hepatocyte growth factor (HGF) increase after two models of renal failure, postnephrectomy, and following CCL4 (chemokine [C-C motif] ligand 4) injection, and this increase supports a role for HGF in renal repair.[36] Exogenous EGF has been shown to enhance renal tubular cell regeneration and to lessen the severity and duration of hypoxia and toxin-induced renal failure. EGF receptor levels increase within hours of ischemic injury in the rat. Elevation of soluble EGF occurs along with morphologic evidence of tubular injury within 12 hours of ischemia, which is followed by cell proliferation and a decrease in soluble EGF by 24 to 48 hours after ischemia.

Alterations in Cell Membranes

Membrane phospholipids have a structural function and affect membrane permeability, as well as the activity of membrane transport systems.[37] These compounds are regulated in part by the activity of phospholipases, which release free fatty acids from phospholipids. Several mechanisms related to acute cell injury may alter phospholipase activity and thereby change membrane phospholipids and membrane integrity: altered intracellular calcium homeostasis, depletion of ATP, and lipid peroxidation.[33] Increased phospholipase activity has been associated with an abnormal increase in permeability of the inner mitochondrial membrane, which ultimately results in disruption of mitochondria and loss of the ability to produce adequate energy.

Cellular Calcium Homeostasis

Increased intracellular calcium is commonly found in cell injury. It is not, however, a consistent finding in all models of renal injury.[38] Techniques to study changes in the subcellular distribution of calcium have allowed time-related changes to be assessed. In the rat proximal tubule, steady-state hypoxia is accompanied by a prompt increase in cytosolic free calcium that precedes the appearance of membrane damage.[29] The increase in calcium is reversed with reoxygenation. Increased cellular calcium may activate phospholipases, as previously mentioned; alter the cytoskeleton and cause injury by allowing cell swelling; or affect membrane permeability at the plasma membrane, the mitochondrial membrane, or the endoplasmic reticulum. Alterations in mitochondrial function that occur as a result of calcium loading of this organelle have been extensively studied. Excess mitochondrial calcium is associated with changes in the permeability of the inner mitochondrial membrane with loss of the electrochemical gradient and the capacity for oxidative phosphorylation. In addition, changes in enzyme activity and mitochondrial levels of nucleotides may exist.

Production of Free Radicals

Renal cell damage induced by inflammation or oxygen deprivation may be mediated, in part, by oxygen free radicals that are generated by several cell processes, including accumulation of long chain acyl-CoA as a result of

mitochondrial dysfunction. The net result is increased intracellular calcium and, ultimately, changes in membrane-related functions.[32]

Tubular Cell Energy Metabolism

After exposure to a variety of nephrotoxins or ischemia, renal cortical ATP levels are reduced even before changes in membrane integrity and cell death occur.[39] In ischemic injury, alterations in renal perfusion may result in decreased oxygen delivery to tubular epithelium. Direct mitochondrial damage has been postulated to be the primary event in many forms of nephrotoxic injury.[32] Other nephrotoxins interfere with energy production by the inhibition of enzymes along the citric acid cycle. In this way, toxins impair energy production. ATP levels decrease immediately after ischemia, with concomitant increases in ATP hydrolysis products. Reperfusion is associated with a gradual increase in cell ATP levels.

Classification of Acute Glomerulotubular Dysfunction

Hemodynamically Mediated Acute Kidney Injury

Renal hypoperfusion with ischemia is a common form of acute renal damage, especially in the setting of the ICU. This form of renal injury is often accompanied by oliguria and results from alterations in renal perfusion after a period of hypoxia, hypotension, cardiac dysfunction, or any condition that promotes hemodynamic instability, decreased effective plasma volume, or both states. This condition is commonly referred to as *acute tubular necrosis* because it is characterized by necrosis of tubule cells; however, this is a nonspecific term that may also define nephrotoxic injury. A preferred term is *vasomotor nephropathy* or *hemodynamically mediated renal failure*.[40] The same physiologic alterations that initiate renal injury in this form of nephropathy may potentiate renal failure in conditions whose primary inciting event may not have been vascular.

Vasomotor nephropathy commonly follows a period of renal compensatory changes that may be termed *prerenal failure,*[9] which are discussed in the preceding section on physiology. When the kidney has fully used normal compensatory mechanisms, renal oxygen delivery is critically impaired, and this impairment results in cell damage or tubular cell necrosis. Thus it is apparent that acute tubular necrosis is the end result of a continuum of renal adaptive mechanisms. Acute cortical necrosis is an exaggerated and more advanced form of renal ischemia.

When vascular or hemodynamic abnormalities persist or are profound, renal compensatory mechanisms are unable to preserve RBF and maintain sufficient oxygen delivery and GFR. At a mean renal perfusion pressure of 80 mm Hg, afferent arteriolar dilation is maximal, and below these systemic pressures, RBF dramatically declines.[9,40] In addition, loss of the ability to autoregulate as a result of ischemia may cause further damage. Renal cell injury develops as the result of deficient oxygen delivery, depletion of cellular energy, loss of membrane integrity, and release of reactive oxygen species. Without sufficient oxygen, the kidney cannot support cell functions that maintain architectural integrity and complex transport functions.

Although total RBF is decreased in vasomotor nephropathy, outer cortical blood

flow is preferentially reduced. The medulla is not spared, however, because of its increased susceptibility to alterations in renal perfusion.[41] Oxygen delivery to this segment of the kidney is precarious. Medullary partial pressure of oxygen (PO_2) is approximately 10 mm Hg in the rat and dog. This oxygen level approaches the critical minimum level required to support oxidative phosphorylation and ATP synthesis for cell function. In general, the proximal tubule sustains the greatest injury. The renal arteriogram of human subjects with vasomotor nephropathy reveals marked narrowing of the arcuate arteries and absence of peripheral vasculature, providing further evidence for the marked vascular resistance enhancement.[40]

The primary event in vasomotor nephropathy is injury of the renal tubule. The initiation of this injury, however, is microvascular in origin. Maximal renal compensation with marked efferent and afferent arteriolar vasoconstriction reduces glomerular plasma flow with resulting hypofiltration and compromises postglomerular blood supply to the renal tubule. Tubular cell necrosis with sloughing of tubular cells into the lumen results in obstruction of flow and back leakage of filtrate through the injured epithelium. Alterations in tubular cell function in cells receiving sublethal or lethal injury increase fluid and salt delivery distally, and this increase signals the glomerulotubular feedback system to cause vasoconstriction of the afferent arteriole and limit the fraction of plasma filtered at the glomerulus.[40] Although the initial reduction in GFR is the result of decreased RBF and tubular factors such as obstruction and back leakage, continued hypofiltration during the maintenance phase is related primarily to continued vasoconstriction and renal hypoperfusion.[40] Recovery from postischemic AKI is biphasic. Initially, an increase in GFR occurs with relief of tubular obstruction and, subsequently, improved filtration in association with renal vasodilation.

Oliguria in the presence of renal hypoperfusion has been referred to as acute renal success by investigators who propose that the response of an intelligent organ to a perceived reduction in blood flow is to reduce fluid and electrolyte losses by vasoconstriction to reduce the fraction of plasma filtered and by maximal reabsorption of fluid and salt to restore the circulation. In addition, increased distal delivery of water and solutes because of tubular cell necrosis reflects failure of the renal tubule to absorb what is filtered. The appropriate response of an intact nephron is to reduce filtration by release of angiotensin II into the interstitium. Angiotensin II mediates arteriolar vasoconstriction, which decreases glomerular plasma flow, and retraction of the glomerular tuft, which reduces Kf, the net effect being decreased glomerular filtration.[41]

The classic form of hemodynamically mediated AKI was oliguric by definition; however, nonoliguric acute vasomotor nephropathy is increasingly recognized.[41,42] This form of less severe disease has been referred to as attenuated acute tubular dysfunction and has allowed the recognition of three stages of AKI that actually represent a continuum of worsening disease: First, abbreviated renal insufficiency occurs after a single event of renal hypoperfusion, such as aortic cross-clamping, in the face of adequate volume repletion and systolic blood pressure (SBP). This syndrome is characterized by an acute drop in the GFR with gradual return to normal within a few days. The inability to concentrate the urine or to conserve sodium provides evidence of tubular injury. The second phase or form is referred to as overt renal failure. An example of this situation is aortic cross-clamping followed

by continued renal hypoperfusion because of poor cardiac function. A more prolonged period of hypofiltration lasts for several days to weeks with a gradual return of the GFR. If recovery of renal perfusion is impaired by repeated episodes of ischemia/hypotension, sepsis, or hypoxia, the third pattern may be observed in which a protracted course may be observed and chances for recovery may be doubtful.[42] One situation in which the last example could exist is aggressive hemodialysis (ultrafiltration) with hypovolemia and, consequently, renal hypoperfusion in the recovering phase of renal failure. Clinical experience has supported this theory. Patients with multiple renal insults have a more protracted course and increased morbidity.[43]

Using the updated Schwartz formula for estimate of creatinine clearance (eGFR) in infants and children, a modified RIFLE classification (pRIFLE) has been developed. The updated Schwartz formula is as follows[44,45]:

$$\text{eGFR} = 0.413 \cdot [\text{height (cm)}]/[\text{sCr (mg/dL)}] \qquad \textbf{Eq. 75.2}$$

The pRIFLE classification is defined by the percentage reduction in eCrCl or the amount of diminishing urine output[2] (Table 75.1).

TABLE 75.1

pRIFLE Classification

pRIFLE	Estimated CrCL	Urine Output
Risk	25% decrease	<0.5 mL/kg/h for 8 hours
Injury	50% decrease	<0.5 mL/kg/h for 16 hours
Failure	75% decrease	<0.3 mL/kg/h for 24 hours or anuric for 12 hours
Loss	Persistent failure >4 weeks	
End-stage renal disease	Persistent failure >3 months	

Treatment of Acute Kidney Injury

Prevention/Attenuation of Acute Renal Failure

Prevention or attenuation of ARF has been the subject of numerous studies, as most agree that protection of the kidney from damage or enhancing recovery after damage would be preferable to the currently available supportive therapies. Primary prevention of AKI in the ICU is limited to those conditions in which the timing of injury is predictable, such as exposure to radiocontrast dye, cardiopulmonary bypass, nephrotoxic medications, or chemotherapy. In contrast to most cases of community-acquired AKI, nearly all cases of ICU-associated AKI result from more than a single insult.[46] Protective agents have been studied extensively with animal models of acute renal injury. Some of these agents have ultimately been used in clinical situations with variable success. In general, methods to reduce renal injury have been aimed at manipulation of RVR or alteration of the metabolic processes of the renal tubular cell.

Dopamine

Dopamine, when infused in low intravenous doses, increases RBF, GFR, and sodium

excretion. In the past, clinicians frequently used "renal dose" dopamine in the hopes that such a maneuver might attenuate renal injury and improve survival. In addition, clinicians often interpret an increase in urinary output as proof that these two assumptions are valid. Dopamine stimulates both dopaminergic and adrenergic receptors. As such, dopamine may affect renal blood flow by direct vasodilation (dopamine receptors), by increasing cardiac output (β-receptors), or by increasing perfusion pressure. Of particular interest is its action on dopamine 1 (D1) receptors, which are abundantly distributed throughout the renal vasculature.[47] Stimulation of D1 receptors results in vasodilation by means of receptor coupling with cyclic adenosine monophosphate (cAMP) and calcium flux generated by protein kinase A. In addition, D1 receptors are also found within the brush border and basolateral membranes of the proximal tubule; medullary ascending limb of the loop of Henle; distal tubule; and cortical collecting ducts where agonist induces a decrease in sodium, phosphate, and bicarbonate absorption. D1 receptors have also been localized to the macula densa where they may modify renin production.[47] Dopamine inhibits the Na/K-ATPase along the nephron. Interestingly, this action would be expected to decrease the oxygen consumption of the renal tubule; thus it would be less susceptible to ischemic or hypoxic injury. Dopamine 2 (D2) receptors are present along the renal tubule. In the inner medulla, a subclass, D2k is coupled to prostaglandin E2 and attenuates the action of antidiuretic hormone (ADH) in this segment.

Dopamine in the dosage range of 0.5 to 2 μg/kg/min increases RBF by 20% to 40%. The GFR increases by 5% to 20%, an effect related to enhanced glomerular ultrafiltration by a preferential vasodilation at the afferent arteriole. This is thought to be related to a dopamine-induced increase in local angiotensin production, which attenuates the dopamine-induced vasodilation at the efferent but not the afferent arteriole. The increase in medullary blood flow observed with dopamine results in a decrease in the urea concentration within the medullary interstitium and contributes to the limited concentrating ability of the dopamine-stimulated renal tubule.

The observed increase in urinary flow is thought to be related primarily to the tubular actions rather than the vascular actions of dopamine. At higher doses, dopamine stimulation of receptors results in decreased sodium and fluid excretion, as well as renal vasoconstriction. Dopamine clearance is decreased in the presence of renal or liver dysfunction.

Despite these descriptive studies suggesting the possible benefit of low-dose dopamine infusion in the setting of evolving AKI, the 2012 iteration of the Surviving Sepsis Campaign guidelines state with a GRADE methodology grading of 1A (strong recommendation, strong evidence) that low-dose dopamine should not be used for renal protection.[48] A large randomized trial and meta-analysis comparing low-dose dopamine to placebo found no difference in either primary outcomes (peak serum creatinine, need for renal replacement, urine output, time to recovery of normal renal function) or secondary outcomes (survival to either ICU or hospital discharge, ICU stay, hospital stay, arrhythmias).

Dopamine may inhibit thyrotropin hormone release from the hypothalamus and have immunosuppressive effects through its inhibition of release of the lymphotropic factor prolactin. Dopamine should be used cautiously in neonates because the renal vascular response to dopamine is age dependent,[49] although administration of dopamine (0.5 to 2 μg/kg/min) to premature neonates with

respiratory distress syndrome and renal insufficiency was reported to result in improved creatinine clearance without major side effects.

Diuretics

Intravenous diuretics have been frequently used in the intensive care unit to ameliorate fluid overload by increasing urine output.[50] This widespread use of loop diuretics in the face of impending renal failure has been ascribed to a combination of animal and human data. Loop diuretics decrease renal vascular resistance and increase renal blood flow.[51] In addition, loop diuretics inhibit the sodium/potassium chloride cotransporter system (NKCC2), thereby reducing active oxygen transport and potentially reducing oxygen consumption and thus limiting ischemic injury to the outer medullary tubules. Indeed, furosemide has been shown to decrease renal oxygen consumption in critically ill patients.

Mannitol may attenuate renal failure if it is given before the insult or immediately afterward.[52] Loop diuretics, such as furosemide, if given along with a potentially nephrotoxic agent, may increase the renal excretion of the agent and reduce associated nephrotoxicity. Mannitol has been shown to ameliorate nephrotoxicity related to gentamicin, amphotericin B, cisplatin, and myoglobin. A specific beneficial effect is doubtful, however, because acute saline loading alone provides similar protection. When tubular obstruction plays a major role, mannitol may increase tubular flow enough to wash obstructing debris downstream. It seems reasonable to use mannitol and potentially furosemide in the initial phases of oliguria when AKI may not be established; however, these agents provide little benefit and may increase toxicity in sustained oliguria as a result of tubular necrosis.

Calcium Entry Blockers

These agents may prevent renal insufficiency through their vasodilatory action on renal vasculature, as well as inhibition of calcium entry. The calcium channel blockers verapamil, nitrendipine, diltiazem, and nisoldipine have been administered to various animal models of ischemic injury with some success in the prevention or attenuation of renal failure. Minimal protection is observed, however, if they are administered after ischemia.[52] Calcium entry blockers had a beneficial effect in endotoxin-mediated AKI. This effect was postulated to be a result of an antagonism of platelet-activating factor.[53] The perfusion of cadaveric renal grafts before transplantation with diltiazem was associated with improved graft survival compared with control subjects.[54] Preoperative administration of calcium channel blockers to adults undergoing cardiac surgical procedures did not provide any obvious protection from the development of AKI.[55]

Prostaglandins

Vasoconstrictive forces in the renal vasculature may result from the action of vasoconstrictor prostaglandins and are counteracted by the vasodilatory substances.[56] Infusion or stimulation of the vasodilatory prostaglandins or inhibition of the vasoconstrictor prostaglandins seems to be a reasonable approach. Prostacyclin provided protection during ischemia in a rat model.[56] Administration of the thromboxane synthetase inhibitor OKY-046 partially ameliorated hypofiltration in a rat model of ischemic renal failure.[57] In addition, the administration of the free

radical scavenger's dimethylthiourea and superoxide dismutase attenuated renal insufficiency and reduced thromboxane levels.

Renin-Angiotensin Antagonists

Administration of saralasin, an angiotensin II receptor antagonist, either before or after ischemia was not beneficial in the rat model. Blockade of angiotensin production by the conversion of enzyme inhibition with enalapril or captopril was not successful in preventing AKI.[58] Whereas captopril did prevent a fall in RBF, it also results in a drop in GFR.

Adenosine and Adenosine Triphosphate

Renal ischemia results in the depletion of cellular adenine nucleotides and increased levels of adenosine, an agent implicated as a mediator of local renal vasoconstriction.[59] Adenosine may also have protective tubular effects during ischemia because it inhibits solute reabsorption in the medullary thick ascending limb of the loop of Henle. Theophylline, a competitive inhibitor of adenosine receptors, partially prevents the hypofiltration following ischemia in the rat.

Infusion of ATP-magnesium chloride (ATP-$MgCl_2$) after renal ischemia promotes more rapid cellular recovery and attenuates renal injury.[59] In animal models, exogenous ATP, adenosine diphosphate (ADP), adenosine monophosphate (AMP), and adenosine preserve renal tubular cell metabolism during anoxia by protecting the membrane from disruption and providing precursors for rapid synthesis of ATP during reperfusion.

Atrial Natriuretic Factor

Atrial natriuretic factor (ANF) has direct effects on glomerular hemodynamics and GFR.[60] ANF dilates arcuate, interlobular, and proximal afferent arterioles, and it relaxes mesangial cells.[61] In a rat model of rhabdomyolysis, administration of ANF improved GFR and enhanced sodium and water excretion. In addition, ANF improved GFR and maintained cell energy levels during ischemic injury.[62] ANF preserves glomerular filtration and cellular ATP levels in experimental models of AKI by its effect on glomerular hemodynamics.

Free Radical Scavengers

Reactive oxygen species have been proposed as a cause of cellular injury in many forms of AKI. The conversion of xanthine to hypoxanthine during reoxygenation produces reactive oxygen species. Antioxidants and xanthine oxidase inhibition (allopurinol) have proved to attenuate renal injury in many models of AKI.

Thyroxine

Thyroxine reduces renal injury in a number of experimental models when given before the injury, immediately after, or 24 hours after ischemia. The mechanism by which thyroxine preserves both glomerular and tubular function is not completely understood; however, the rate of recovery of cellular ATP levels was much more rapid in animals given thyroxine after ischemic AKI. Isolated mitochondria from rats subjected to 45 minutes of ischemia exhibited decreased mitochondrial ADP

transport. Administration of thyroxine was associated with significantly enhanced ADP transport.[63] The investigators speculated that part of the ATP depletion associated with ischemic injury might be the result of decreased mitochondrial uptake of the ATP precursor, ADP. The administration of thyroxine at 5 to 6 ng/kg/day for 5 to 10 days in eight children with AKI resulted in the recovery of renal function in all but one child, who died of the original disease.[64]

Glycine and Alanine

The amino acids glycine and alanine have been shown to have cytoprotective effects against injury in anoxia-hypoxia and chemotherapy-induced renal failure. The mechanism of cytoprotection is not understood but does not appear to involve preservation of intracellular ATP levels. Studies performed in cultured proximal tubular cells indicate that glycine and alanine may stimulate the expression of HSP genes and increase HSP proteins, which protect cells from injury. The cytoprotective effect was not observed with other amino acids and was independent of cellular ATP levels in this model of renal injury.[65] Incubation of isolated renal tubules with glycine during hypoxia was associated with increased levels of glutathione, as well as increased cell ATP, although these did not appear to account fully for the protective effect of glycine. In addition, administration of glycine prevented renal injury in rats treated with nephrotoxic doses of cisplatin.[66]

Acute Kidney Injury: Clinical Impact

Severe deterioration of kidney function can have a profound effect on body fluid homeostasis and on blood pressure. The nature of these alterations often requires intensive care management regardless of the precise underlying diagnosis. A wide variety of kidney diseases may result in AKI. The most urgent aspects of AKI are (1) hyperkalemia, (2) severe hypertension, (3) severe plasma and extracellular volume expansion leading to heart failure and pulmonary edema, (4) unremitting metabolic acidosis, (5) hypocalcemia/hyperphosphatemia. Each of these can be viewed as an indication for intensive care and consideration of dialysis.[67] Additionally, the presence and degree of fluid overload (FO) has been shown to be a predictor of survival at the initiation of renal replacement therapy (RRT) and is now considered an important indication for intervention.[68-71]

Hyperkalemia

The major reason for the development of hyperkalemia (serum potassium concentration more than 6 mEq/L) is the release (or infusion, or both) of potassium into the extracellular space at a rate greater than the kidney's ability to excrete potassium. Further, the intracellular potassium is in the concentration range of 140 to 150 mEq/L, adding to the total source of potassium. The fact that AKI and oliguria have developed does not mean that hyperkalemia will develop. By the same token, hyperkalemia may develop rapidly in situations of extensive tissue destruction even without oliguria and “full-blown” AKI. Thus in the clinical situation of a crush injury or the tumor lysis syndrome, hyperkalemia should be anticipated and careful anticipatory monitoring begun.

Severe Hypertension

Hypertension is frequently associated with kidney disease. The two main mechanisms by which kidney disease leads to hypertension, especially accelerated hypertension, are (1) plasma volume expansion caused by the failure to excrete sodium chloride and water and (2) hyperreninemia associated with decreased kidney perfusion.

Plasma and Extracellular Volume Expansion

Plasma and extracellular volume expansion are associated with kidney failure. With an abrupt decline in GFR, even “normal” amounts of sodium and water intake expand the extracellular and plasma volumes. Depending on the cardiac status of the patient, the serum albumin level, and the degree of capillary permeability, this extracellular and plasma volume expansion may be manifest as peripheral edema, hypertension, or congestive heart failure and pulmonary edema. In situations of hypertension or congestive heart failure, the treatment involves two principles. The first is to reduce to as low a level as possible the amount of sodium and fluid the patient receives. This requires attention to diet, intravenous or hyperalimentation solutions, and drugs. The second principle is to remove extracellular fluid. If the patient's kidney function permits (glomerular filtration of approximately 15 mL/min or higher), then diuretics, especially loop diuretics such as furosemide, bumetanide, or ethacrynic acid, will help to stimulate a diuresis that should improve the blood pressure or the congestive heart failure. The addition of thiazide diuretics prior to the use of loop diuretics may potentiate the effectiveness of loop diuretics allowing for a greater diuresis.[72] In children with more severe kidney disease, diuretic therapy does not result in diuresis, and dialysis will be necessary.

Severe Metabolic Acidosis

The kidney is responsible for the excretion of hydrogen ion and the regeneration of bicarbonate. When kidney function rapidly deteriorates, then the extracellular concentration of hydrogen ion increases, and this increase leads to acidosis and low serum bicarbonate concentrations. This problem is exacerbated by conditions that increase the production of hydrogen ion and its release into the extracellular fluid. Conditions such as sepsis, severe trauma, burns, extensive abdominal disease or surgery, high chloride-containing intravenous fluids, and hemolysis are all examples in which hypoxia, high hydrogen ion production or release into the extracellular space, and a decline in RBF and the GFR are combined. The result is severe metabolic acidosis (see also Chapter 76).

Hypocalcemia/Hyperphosphatemia

Hypocalcemia arises from hyperphosphatemia as a result of dietary load, cellular breakdown, and reduced kidney phosphate excretion; reduced synthesis of calcitriol; down-regulation of skeletal cell receptors for parathyroid hormone; and acidosis.[73]

Hyperphosphatemia may not be recognized, for the plasma phosphorus level is not contained on any of the classic “lab panels” as directed by Medicare; it therefore needs to be thought of and sought out for identification.

Uremia

The symptoms of uremia are frequently vague and difficult to quantitate. They include central nervous system (CNS) manifestations such as lethargy, confusion, seizures, and obtundation and also gastrointestinal manifestations such as anorexia, nausea, and vomiting. These symptoms plus metabolic derangements often lead to the initiation of dialysis.

Renal Disposition of Endogenous and Exogenous Compounds

An important consideration in AKI is the role of the kidney in the metabolism, elimination, and detoxification of endogenous and exogenous materials. Any drugs given must be reviewed because the dosing interval or the dose of drug may need to be altered in AKI. Endogenous substances generally are more slowly metabolized or excreted. For example, the hormone gastrin is metabolized by the proximal tubule after being filtered by the glomerulus. The resultant persistent high circulating levels of gastrin may explain the higher incidence of gastritis and ulcer disease seen in patients with kidney failure.

Specific Kidney Diseases That May Lead to Acute Kidney Injury

Hemolytic Uremic Syndrome

Hemolytic uremic syndrome (HUS) is considered to be the most common cause of AKI in children in the world.[74] Whereas this may be correct, it should be recognized that within "westernized" medical systems, AKI is more commonly a consequence of sepsis, cardiac disease, and other comorbid and chronic underlying conditions.[75]

HUS is characterized by thrombotic microangiopathy with platelet aggregation and fibrin deposition in small vessels in the kidney, intestine, CNS, and elsewhere. The hemolytic anemia is related predominantly to shearing of red blood cells as they pass through involved vessels. The syndrome is defined by the triad of microangiopathic hemolytic anemia, thrombocytopenia, and impaired kidney function. In the typical form of the disease, a triggering infectious agent has frequently been reported and is usually accompanied by diarrhea, hence "typical" HUS is usually synonymous with the term *diarrhea-positive* HUS. *Escherichia coli* (0157:H7) has been implicated in a large number of cases of typical (epidemic) forms of HUS.[76] It should be understood that there exist a myriad of causes of HUS (*Streptococcus pneumoniae* infection, usually severe; *Shigella dysenteriae; Citrobacter;* etc.) and that in the absence of verotoxin-secreting *E. coli,* HUS can still occur. Atypical HUS is usually used to describe diarrhea-negative or atypically presenting cases (positive family history, early presentation less than 6 months), although it is increasingly applied to cases of suspected or confirmed complement pathway mutation. A third entity, thrombotic thrombocytopenic purpura (TTP), presents as a pentad of symptoms that overlap with HUS: microangiopathic hemolytic anemia, thrombocytopenia, mild renal impairment, fever, and neurologic disease. HUS may also present with fever and neurologic involvement, making the clinical diagnosis

difficult to distinguish. TTP has now been linked to a deficiency or inactivation of the protease that cleaves von Willebrand factor, ADAMTS13, which can be used to differentiate the two diagnoses.

Clinical Signs

Typical HUS usually presents in “epidemics” and is characterized by a prodrome of bloody diarrhea. Children with HUS are older than 1 year and younger than 10 years (typically, 18 months to 3 years). The important presenting features of bloody diarrhea, fever, lethargy, decreased urine output, and pallor should lead to a suspicion of HUS. Laboratory evaluation will verify the diagnosis. Atypical HUS is caused by complement pathway mutations (most commonly factor H or factor I but also membrane cofactor protein, C3-convertase, and factor B), which are responsible for promoting the decay of the spontaneously activating alternative complement pathway. The alternative complement pathway normally assists the body in discriminating between host and foreign cells, and mutations lead to an uncontrolled activation. The development of HUS has also been associated with oral contraceptives and calcineurin inhibitors.[76,77] The final common pathway, regardless of the initiating agent, is endothelial cell injury, platelet activation, and activation of the alternative complement pathway.[78]

Once the endothelium is injured and the subendothelial region is exposed, a sequence of events is set into motion that amplifies the initial endothelial damage. Platelets adhere to the subendothelial space, and a release reaction follows that activates additional platelets and initiates fibrin deposition. Both endothelial cell and platelet factors are involved in the propagation of intraglomerular fibrin deposition and coagulation. Direct injury of the endothelial cell may initiate coagulation by release of tissue factor or exposure of the basement membrane. Evidence suggests that the endothelial cells in patients with HUS have reduced ability to produce prostacyclin (PGI_2), a potent vasodilator and inhibitor of platelet aggregation. Some patients with HUS lack a plasma factor that stimulates PGI_2 production. In addition, there is decreased glomerular fibrinolytic activity because of a circulating inhibitor of plasminogen activator. Interestingly, this fibrinolysis inhibitor is removed from the circulation by dialysis.[79] Platelet count and survival time is decreased in patients with HUS, and occasionally there is evidence of platelet activation.

Hemolysis may be brisk and may require transfusions on a daily basis. The aim of transfusions during the period of hemolysis should be to prevent heart failure and not to return the hematocrit value to normal. Thrombocytopenia may be severe but only rarely results in significant bleeding, and therefore platelets should not be given unless clearly needed to stop bleeding or in anticipation of invasive (especially vascular) procedures. Some have suggested that platelets play an important role in the pathophysiology of this disorder. It is further suggested that infusing platelets may actually prolong or worsen the intravascular deposition characteristic of HUS.

Complications

Other organ system involvement may lead to serious complications. CNS involvement may reflect the metabolic effects of uremia and can be manifested by lethargy, somnolence, stupor, or coma. Seizures, paresis, and even CNS hemorrhages can result from vascular damage and CNS vessel occlusion.

Gastrointestinal involvement has also been well documented. Liver enzyme elevations, abdominal pain, intestinal obstruction, and bowel perforation have all been reported. These possibilities must be considered and evaluated when appropriate. In some instances, the diagnosis of HUS has been made after abdominal exploration.

Therapy

Therapy has been supportive, aimed at preventing deterioration and carefully managing complications such as AKI, anemia, CNS, and abdominal symptoms. Heparin, fibrinolytics, and antiplatelet drugs (aspirin, dipyridamole) have all been attempted. In general, reports demonstrate lack of benefit and, in the cases of heparin and fibrinolytics, increased harm from increased bleeding. Platelet transfusions can enhance thrombosis in microvasculature, so they are not indicated unless there is active bleeding. The HUS outbreak in Germany that resulted in a large number of deaths has shed light on the understanding of treatment interventions regardless of classic or atypical types of HUS.[80]

In severe cases of HUS, plasma exchange (PE) may be indicated, with various studies citing an increase in survival between 10% and 78%[81-83] versus supportive care alone. However, complete hematologic (normalization of lactate dehydrogenase [LDH], platelet count) and renal response rates are lower in patients with identified complement mutations, as the underlying complement dysregulation and thrombotic microangiopathic processes likely persist despite PE.[84] Eculizumab, a C5 complement inhibitor that prevents downstream formation of the membranolytic membrane attack complex (MAC), has been used in atypical HUS with good and promising efficacy. The medication is costly, and randomized controlled trials have not been completed to determine optimal pediatric dosing intervals or duration, although several studies are ongoing. The majority of published data use an eculizumab induction dose of 900 mg once a week for 4 weeks, followed by maintenance 1200 mg every 2 weeks for 1 year in patients >40 kg.[84] Cataland and Wu[83] proposed a treatment schema in adults of suspected atypical HUS or TTP cases beginning with PE and continuing if the patient is deemed a good responder by hematologic and renal recovery criteria. If the patient is a nonresponder after a period of 3 to 5 days on PE, they recommend then basing treatment on ADAMTS13 activity; if normal, the patient is treated as atypical HUS with eculizumab, and if ADAMTS13 is deficient, the patient is treated with immunosuppressive therapies. Case series in the pediatric literature report good neurologic and renal outcomes after use of eculizumab; however, dosage and duration are not uniform. Further prospective studies are needed to determine the most cost-effective pediatric dosing regimen and whether outcomes in pediatric patients are improved.

Prognosis

The prognosis for the “typical” form of HUS is good. Most series report 3% to 5% mortality rates and an additional 3% to 5% with chronic changes such as chronic kidney disease, persistent hematuria/proteinuria, and chronic hypertension. Thus more than 90% of children with the typical form of HUS recover completely.

In the face of AKI, many of the therapies (red blood cell [RBC], platelet infusion, fresh frozen plasma) result in volume to the children, potentially increasing the risk

of fluid overload. Further, the plasma components of packed red blood cells (PRBCs) are hyperkalemic, acidotic, and hypocalcemic. Therefore, transfusing PRBCs to a patient with AKI may induce not only fluid overload but also significant and even lethal electrolyte disturbances. The use of RRT may be needed to offset these potential risks.

Acute Glomerulonephritis

Nearly every form of glomerulonephritis has been reported to present as AKI (Box 75.2). In some instances the kidney insufficiency may be the result of an immunologic process leading to acute inflammation (eg, acute postinfectious glomerulonephritis). In others, intravascular volume depletion may play a prominent role in AKI (eg, minimal change nephrotic syndrome).

Box 75.2

Glomerular Disease Associated With Acute Kidney Injury

Hypocomplemententemic (low C3)

- Acute postinfectious glomerulonephritis

- Henoch-Schönlein purpura
- Immunoglobulin A nephropathy
- Wegener granulomatosis
- Goodpasture syndrome
- Membranous nephropathy

Hemolytic-uremic syndrome

Minimal-change nephrotic syndrome

In general, glomerulonephritis is initiated by immunologic events within the glomerulus followed by mechanisms that result in damage to the glomerulus.[85] Glomerular disease results from the deposition of immune complexes composed of

(1) antibodies to nonkidney antigens that localize within the glomeruli and form in situ immune complexes; (2) circulating soluble immune complexes that are trapped within the mesangium or subendothelial space; or (3) antibody to antigens within the glomerulus, either as normal glomerular antigens or as neoantigens induced by inflammation or infection. Antibody deposits promote injury by activation of inflammatory cells or by their direct interaction with glomerular cells. The result is mesangial cell proliferation, capillary wall and basement membrane injury, and extracapillary proliferation of epithelial cells, a process known as crescent formation.

Immune complexes mediate glomerular injury in two ways: through direct membrane damage by the MAC complex or by stimulation of glomerular localized inflammatory cells.

Salt and water retention commonly observed with acute glomerulonephritis is the result of a decreased GFR, not increased tubular reabsorption, as once proposed. The renin-angiotensin system is thought not to play a role in the positive salt and water balance. In general, the presentation of glomerulonephritis as AKI implies a virulent form of disease known as rapidly progressive or crescentic glomerulonephritis. Although rapidly progressive refers to a clinical characteristic and crescentic to a pathologic feature, the two are commonly coincidental in the presentation of AKI. A classification of rapidly progressive glomerulonephritis is presented in Box 75.3. Four prototypical conditions serve as examples of acute kidney disease that may result in the need for intensive care.

Box 75.3

Classification of Rapidly Progressive Crescentic Glomerulonephritis

Pulmonary renal syndromes

- Churg-Strauss syndrome

Postinfectious

Henoch-Schönlein purpura

Immunoglobulin A nephropathy

Membranoproliferative glomerulonephritis

Acute Postinfectious (Streptococcal) Glomerulonephritis

This condition is well known to pediatricians. An association between glomerulonephritis and scarlet fever was known in the 18th century. In the early 20th century, however, a clear connection between streptococcal infections and glomerulonephritis was established. The disease most frequently occurs between the ages of 2 and 12 years. It is seen as a sporadic event or in epidemics. It appears that only certain strains of streptococci lead to glomerulonephritis, thus the term *nephritogenic streptococcus*.[86] The more recent term is *postinfectious glomerulonephritis (PIGN)* due to the fact that no longer does *Streptococcus* cause the majority of the cases of PIGN cases.

The mechanisms by which nephritogenic streptococci cause glomerular injury are similar to that seen with "shunt nephritis." It is generally accepted that immune complexes, with the participation of complement and other inflammatory mediators, cause glomerular inflammation. The precise nature of the bacterial antigen and its site of formation (circulation compared with in situ in the glomerulus) remain areas of study.

Clinical Signs

The usual sites of infection are the upper respiratory tract, skin, or both. A long-standing observation is that the latent period is 7 to 14 days if the infection is in the upper respiratory tract and 21 to 40 days if the infection is on the skin. Subclinical cases may be common; they are estimated to be 2 to 19 times as frequent as clinical cases. Symptomatic cases usually present with an acute nephritic syndrome: edema, hypertension, hematuria, and oliguria. Other important clinical features include proteinuria, red cell casts, and abnormal urinary red cell morphologic findings, all markers of glomerular injury. Pulmonary edema may also be present, especially if significant salt and water retention are present and if hypertension is severe. Nonspecific findings include malaise, anorexia, abdominal pain, nausea, and vomiting. (This presentation is seen with other forms of acute glomerulonephritis.) Patients may have AKI.

Laboratory Findings

Laboratory findings at the time of presentation or early in the course include high serum IgG levels and low serum complement levels, especially C3 and CH50. In general, the alternate pathway of complement is the mechanism of complement activation, although on occasion C2 and C4 may be depressed as well. Complement levels return to normal in 4 to 6 weeks. Therefore if complement levels remain depressed for 6 to 8 weeks after the onset of acute glomerulonephritis, another diagnosis should be strongly entertained (systemic lupus erythematosus or membranoproliferative glomerulonephritis). The definitive diagnosis is based on renal biopsy that can be performed easily adding clarity to the diagnosis.

Treatment

Treatment is based on the patient's symptoms and is directed at preventing or reducing salt and water retention and hypertension. All patients should have salt and water restriction unless dehydration is obvious (an unusual situation). Approximately 50% to 60% of patients require treatment for hypertension. Diuretics,

angiotensin-converting enzyme inhibitors, and potent vasodilators should be considered. Five percent of patients may require dialysis for congestive heart failure, hypervolemia, or encephalopathy.

Prognosis

The long-term prognosis in acute postinfectious glomerulonephritis is a matter of debate. The mortality rate is approximately 0.5%, and death usually results from severe hypertension and encephalopathy or heart failure. A study by Potter and colleagues[87] suggested that the long-term prognosis generally thought to be excellent was in fact not necessarily so. Studies with follow-up of 10 to 15 years suggest that chronic kidney injury develops in approximately 1% of patients. A second consensus conclusion is that the prognosis is better in children than in adults. Longer-term follow-up is needed.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a protean illness affecting many organ systems. In some instances, intensive care is needed for aspects of SLE such as nephritis, cerebritis, carditis, serositis, or sepsis.

Even within a relatively narrow aspect of SLE such as nephritis, great heterogeneity exists. Glomerulonephritis develops in approximately 75% of patients with SLE.[88] This may range from mild hematuria and proteinuria to nephrotic syndrome and rarely to rapidly progressive kidney failure. The patterns of lesions in lupus nephritis are varied. The World Health Organization (WHO) has classified lupus nephritis based on light microscopy into five categories: (1) minimal disease, (2) mesangial disease, (3) focal proliferative glomerulonephritis, (4) diffuse proliferative glomerulonephritis, and (5) membranous nephropathy. These five categories have been further subdivided to reflect activity (eg, cellular proliferation, crescents, thrombi, presence of tubulointerstitial disease) and chronicity (eg, sclerosis, fibrosis, tubular atrophy). Combining these pathologic categories with a small number of clinical predictors of poor outcome such as age younger than 24 years, male gender, and decreased kidney function on presentation has permitted a more careful assessment of therapeutic interventions.

Clinical Signs

The broad variation in clinical manifestations may reflect individual expression of similar immunopathologic mechanisms or different immunopathologic mechanisms presenting as a similar constellation of clinical manifestations.[89] It is clear that SLE represents the overproduction of antibodies against multiple “self”-antigens. Patients with lupus have high titers of antinuclear antibodies and in particular anti-double-stranded DNA antibodies, which are often seen in SLE nephritis. Work by Hobbs and associates demonstrated a high presence of antiphospholipid antibodies placing the child at risk for clotting. This clotting risk may be accentuated in the face of nephrotic syndrome or the use of birth control pills.[90] The factors that lead to the abundant production and activation of relevant B cells are unclear. Certainly hormonal influence must be important because most patients with SLE are women. Environmental factors may be important in cases of SLE induced by drugs or viruses and the known association of SLE with ultraviolet light exposure. Other important

factors are suggested by the higher than normal T helper/T suppressor cell ratio. Many of these act in concert to result in abundant antibody production and the deposition of complexes in target organs such as the kidney.

Clinically, patients with SLE nephritis who require intensive care probably have rapidly progressive glomerulonephritis or AKI. Their presentation includes many of the following features: hypertension; active urinary sediment with proteinuria, hematuria, and casts; oliguria or rarely anuria; intravascular volume expansion; and declining kidney function with rising serum creatinine, hyperkalemia, and metabolic acidosis. Unlike the glomerulonephritis described previously, treatment should include management of kidney dysfunction as previously outlined and management aimed at the SLE itself. Kidney biopsy is useful not only to assess the degree of glomerular involvement as classified by the WHO grading system but also to evaluate for acute tubular necrosis or drug toxicity with tubular damage.[91]

Treatment

In the intensive care setting, treatment directed at rapidly progressive or diffuse proliferative SLE nephritis consists of high-dose bolus corticosteroid (usually methylprednisolone) at a dosage of 10 to 20 mg/kg intravenously (IV) given 3 to 5 times in a daily or every-other-day regimen. This therapy is associated with hypertension. Other treatments have included plasmapheresis, immunosuppressives including azathioprine, cyclophosphamide, mycophenolate mofetil or other alkylating agents, and methotrexate. Over the past decade the use of rituximab and other immune-modulators such as belimumab have been studied in children of varying results, with detailed review elsewhere.[92] Data from the National Institutes of Health and others have suggested significant benefit from cyclophosphamide or mycophenolate mofetil in maintaining kidney function.[93]

Prognosis

The long-term prognosis for children with SLE nephritis is unclear.[89] Regardless, patients and families must expect persistent evidence of kidney injury such as hematuria, proteinuria, hypertension, and even reduced kidney function such as a diminished GFR. Further, patients may have relapsing episodes of nephrotic syndrome or acute glomerulonephritis.

Other Glomerulonephritides

Two other forms of glomerulonephritis may result in the need for intensive care therapy. These are antiglomerular basement membrane (anti-GBM) antibody disease (Goodpasture syndrome) and granulomatosis with polyangiitis (GPA, formerly known as Wegener granulomatosis). Although rare in children, both conditions can result in AKI. Therapy should be directed at the general condition of AKI as discussed previously in addition to specific therapy.

In the case of anti-GBM antibody disease, patients may have both kidney disease and pulmonary disease, often pulmonary hemorrhage. Treatment includes corticosteroids, plasmapheresis, and immunosuppressives, mainly alkylating agents. Despite therapy, end-stage kidney disease develops in some patients. Recurrences of anti-GBM antibody disease in kidney allografts have also been reported but are rare.[94] Vasculitic syndromes associated with kidney disease include GPA and

microscopic polyangiitis (MPA), associated with antineutrophil cytoplasm antibody (ANCA).[95] ANCA is an autoantibody that is found in one of two patterns in many forms of vasculitis and serves as a potentially useful diagnostic tool. GPA, or Wegener granulomatosis, is characterized by granulomatous vasculitis that attacks the respiratory tract including sinuses, trachea and lungs, and the kidneys. This condition may be difficult to diagnose, and biopsy may be the only means of determining the diagnosis if the plasma ANCA is negative. Children often present with nonspecific constitutional symptoms, with glomerulonephritis and pulmonary disease also common at presentation. Cyclophosphamide induction with azathioprine maintenance has been shown to be beneficial in the treatment of the kidney disease of Wegener granulomatosis, and plasmapheresis is also of potential benefit in crescentic forms, although it is not widely used because of frequent complications. Rituximab, a monoclonal antibody to CD20 on B cells, has been approved for the treatment of severe ANCA-associated vasculitis on the basis of the adult rituximab in ANCA-associated vasculitis (RAVE) trial,[96] which showed that a single course of rituximab plus steroid for induction was noninferior to cyclophosphamide followed by azathioprine.

Nephrotic Syndrome and Acute Kidney Failure

AKI is an uncommon complication of primary nephrotic syndrome in children but may occur as a result of intravascular volume depletion, bilateral kidney venous thrombosis, or drug-induced kidney toxicity.[97]

The clinical scenario is one in which the child has a low serum albumin level and edema (increased extracellular volume). These patients have stable and often normal plasma volumes despite low oncotic pressure. Should an acute illness (eg, gastroenteritis) occur, however, intravascular volume depletion and AKI may develop rapidly. Patients with nephrotic syndrome who have fluid losses or are unable to take in fluids should be admitted to the hospital, and intravenous administration of albumin plus maintenance and replacement fluids should be considered. The use of intravenous albumin helps to maintain the intravascular volume and reduces the edema that might develop during fluid therapy. Removal of fluid with diuretics or dialysis/hemofiltration can assist with recovery of function. Placing a vascular access for dialysis in a child with nephrotic syndrome is not without risk. In general, children with nephrotic syndrome have a high risk of clotting, independent of vascular access. The large bore vascular access commonly used for dialysis may potentiate this risk. Use of heparin for thrombosis prevention should be considered in certain high-risk situations.

Tubulointerstitial Disease

Acute Tubulointerstitial Nephritis

Acute tubulointerstitial nephritis (ATIN) is a clinical syndrome characterized by inflammation of the kidney interstitium accompanied by interstitial edema and kidney tubular injury. ATIN may be caused by numerous drugs, infectious agents, and systemic illnesses.[98] A partial list of causes can be found in Box 75.4.

Box 75.4

Primary Causes of Acute Tubulointerstitial Nephritis

Drugs

Infections

Septicemia

Leptospirosis

Candidiasis

Malignant infiltration

Lymphoma

Leukemia

Systemic diseases

Systemic lupus erythematosus

Sarcoidosis

In most cases, ATIN is immunologic in origin. Most understanding of the pathogenesis has been obtained from animal models. Three phases have been described for ATIN. The initial phase involves recognition of a nephritogenic antigen located in the interstitium. The antigen may be a normal component of the interstitium, a modified constituent, drug induced, or infection induced. Loss of host tolerance is thought to be required for the initial phase to occur. The immune regulatory phase is characterized by the activation of T-helper lymphocytes, which induce differentiation of T and B cells that directly injure the interstitium. The inability of the host to counteract this response with T-suppressor cells permits T- and B-cell activation to go unabated. In the effector phase, both humoral and cell-mediated components contribute to tissue injury. Antibodies to tissue antigens promote injury by activation of the complement cascade, chemotaxis, and cell-mediated cytotoxicity. IgE is also produced, which may recruit eosinophils or mast cells. Mononuclear cell infiltration produces tissue injury by release of proteases and lymphokines. Eosinophils also damage surrounding tissue by release of proteases, leukotrienes, and toxic oxygen species.

Several theories have been proposed to explain the reduced GFR: (1) the "clogged drain," (2) the capillary bed, and (3) vascular tone hypotheses. The clogged drain theory proposes that tubular obstruction caused by luminal debris and interstitial edema results in increased pressure in the Bowman space and decreased pressure favoring filtration. Interstitial inflammation results in injury to the blood supply of the tubules (capillary bed hypothesis). Because these vessels are postglomerular, the increased resistance and reduced surface area associated with vessel injury result in an increase in efferent arteriolar pressure and a reduction in the pressure gradient across the glomerulus with a resultant drop in the GFR. Decreased sodium

reabsorption by injured proximal tubular epithelial cells reduces the medullary interstitial osmolality and impairs the ability to concentrate the urine. Thus an increased volume of filtrate is delivered distally, stimulating the juxtaglomerular apparatus to increase angiotensin II production (vascular tone hypothesis). The net result is vasoconstriction and a diminished GFR.

Pathologically, diffuse or patchy infiltration of the kidney interstitium by lymphocytes, plasma cells, and eosinophils and edema of the interstitial space is observed. Eosinophils are usually indicative of an acute phase, whereas epithelioid granulomas with giant cells and fibroblasts or fibrosis indicate chronic disease. Tubules may have mild structural alterations or marked necrosis with loss of brush border. Drug-induced interstitial nephritis is the most common form of ATIN in adults and children. Eight of 13 pediatric patients described in one series[98] and 38 of 57 in another series of children[99] with interstitial nephritis had drug-related causes of ATIN. Numerous drugs have been associated with ATIN. The β-lactam antibiotics are the most frequently associated with ATIN with methicillin being the prototype, although ampicillin is the most common offending drug in pediatric series. NSAIDs are increasingly recognized as a cause of acute kidney dysfunction.

Clinically apparent disease usually develops days to weeks after exposure to the inciting drug or agent but may be immediate.[100] Drug-induced tubulointerstitial disease is localized predominantly to the cortex, whereas infectious or infiltrative disorders more commonly localize to the medulla. The functional abnormality often indicates the primary site of tubular injury. Damage involving mainly the proximal tubule results in the wasting of bicarbonate, phosphate, glucose, amino acids, and uric acid. Distal tubular involvement may be manifest as hyperkalemic kidney tubular acidosis as a result of impaired secretion of both K^+ and H^+. Nephrogenic diabetes insipidus can result with medullary involvement.

Although ATIN is primarily a disease of the kidney interstitium and tubule with lack of glomerular structural alterations, the GFR may also be reduced. Of 13 children described by Ellis and colleagues[98] and Andreoli,[101] 12 had a creatinine clearance of less than 50 mL/min/1.73 m^2. AKI resulting from ATIN may be oliguric. Other clinical signs of ATIN are fever and rash. ATIN usually resolves with removal of the offending agent, although occasionally chronic kidney insufficiency may result.

Cardiorenal Syndrome

Renal insufficiency occurs commonly in adult and pediatric patients with heart failure. Although the mechanisms are not fully understood, diminished cardiac function coupled with renal dysfunction, or the cardiorenal syndrome, has been observed in both the acute and chronic care settings. The phenomenon remains better characterized in adult medicine. Decreased urine output and resultant fluid retention can aggravate heart failure symptoms and contribute to clinical deterioration. Even a modest increase in serum creatinine (ie, >0.2 mg/dL) can predict mortality in adult patients hospitalized for heart failure.[102] The relationship of renal function and heart failure in children has not been well examined. Retrospective data analysis has shown a high incidence of cardiac disease among children who exhibit renal insufficiency while hospitalized, and clinical experience suggests that as in adults, worsening renal function is associated with worse

outcomes among children with heart failure.[103]

Basis for Deteriorating Renal Function

The physiologic interaction of the heart and kidney is complex and not well understood, although it is recognized that disease of one organ system frequently complicates the other. Some have termed this combined cardiac and renal dysfunction the *cardiorenal syndrome*. Renal insufficiency occurring in heart failure patients is usually attributed to a "prerenal state" resulting from diminished cardiac output and renal perfusion. It is hypothesized that deteriorating cardiac output and decreasing renal blood flow trigger neurohormonal activities that lead to fluid retention and increased systemic vascular resistance, causing further progression of ventricular dysfunction. Data from animal studies show that isolated renal ischemia leads to increased pulmonary vascular permeability, suggesting a bidirectional pathophysiologic interaction between the renal and cardiopulmonary systems.[104] Other mechanisms may also contribute to a decline in renal function, including medications being used to support cardiovascular function, such as vasoactive drugs. A study by Price and coworkers[105] reported worsening renal function with the use of dopamine and nesiritide.

There is evidence that right ventricular (RV) dysfunction may be associated with renal venous congestion. Using echocardiographically derived measurements, Testani and colleagues showed that in 151 patients, RV dysfunction remained a significant predictor of change in glomerular filtration rate after controlling for heart rate, hemoglobin, admission serum urea nitrogen, B-type natriuretic peptide level, diuretic dose, length of stay, ejection fraction, cardiac output, tricuspid regurgitation severity, and inferior vena cava inspiratory collapse.[106]

Cardiac Surgery–Related Acute Kidney Injury

AKI is not uncommon following cardiac surgery, and its presence portends a worse prognosis. In a survey of 542 patients who underwent cardiopulmonary bypass to fix their congenital cardiac disease, the rate of acute kidney injury after congenital cardiac surgery was shown to be about 11%.[107] Other studies have found mortality rates to be four times higher in patients with renal failure compared to those without. Studies have shown that a small rise (less than 50%) in creatinine in the first 48 hours could predict a greater than 50% increase in serum creatinine in the next 48 hours. Significant independent risk factors for AKI were bypass time and longer vasopressor use; there was a tendency toward younger age as a risk factor.[108] Cardiac surgery–related AKI has been characterized and described in adult medicine; however, at this time it remains difficult to characterize the exact nature of the injury in the pediatric population. Cardiac surgery–associated acute kidney injury (CSA-AKI) is a significant clinical problem. It results from the interactions between the complicated interventions required in the process of congenital cardiac surgery such as cardiac bypass, use of blood products, the anatomic variability of the congenital cardiac abnormality such as single ventricles, and the surgical correction/palliation of the lesion. It likely involves at least six major mechanisms: exogenous toxins and cytokines, metabolic factors, ischemia and reperfusion, neurohormonal activation, inflammation, and oxidative stress.[109] These mechanisms of injury are likely to be active at different times with different intensity and probably act synergistically.

There are also some data that suggest that at least some of the injury may be pigment related, but this is yet to be substantiated.[110] There have also been attempts at ameliorating the injury with interventions such as *N*-acetyl cysteine, but this has resulted in an increase in bleeding with any benefit yet to be established.[111]

There are, however, newer markers of renal injury such as plasma neutrophil gelatinase-associated lipocalin (NGAL) that are more sensitive than serum creatinine in predicting acute kidney injury. In fact, plasma NGAL at 2 hours after cardiopulmonary bypass (CPB) was the most powerful independent predictor of AKI in patients post-CPB.[112,113] Serum creatinine is an inadequate marker because nearly 50% of renal function has to be lost before its levels are elevated, and serum creatinine does not accurately depict kidney function until a steady state has been reached, which may require several days. Biomarkers such as plasma NGAL may provide for earlier clinical intervention, thereby preventing significant mortality or morbidity. The renal histologic changes in cardiac surgery–related AKI are yet to be well characterized.

Porcine data utilizing experimental cardiopulmonary bypass revealed higher tubular injury scores in kidneys post-CPB relative to controls (median score 1.0 [IQR 1.0-1.0], $p = .019$). AKI was associated with endothelial injury and activation, as demonstrated by reduced *Dolichos biflorus* agglutinin (DBA) lectin and increased endothelin-1 and vascular cell adhesion molecule (VCAM) staining.[114]

Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) is an oncologic emergency that is usually seen when tumor cells undergo rapid decomposition spontaneously or, more often, in response to cytoreductive therapy with the release of large amounts of potassium, phosphate, and nucleic acids into the systemic circulation (see also Chapter 94). Catabolism of the nucleic acids to uric acid leads to hyperuricemia, and a marked increase in uric acid excretion can result in the precipitation of uric acid in the renal tubules and mediate acute renal failure. Despite advances in treatment and diagnosis of cancer patients, large population-based studies have cited a 1-year risk of AKI of 17.5% and a 5-year risk of 27%.[115] Even mild AKI that does not require renal replacement therapy has been associated with increased long-term risk for renal failure and mortality. The levels of phosphorus in malignant cells can be up to four times the levels found in normal cells, and rapid release of these stores can result in hyperphosphatemia, with an increase in serum levels by as much as 2.1 mmol/L in children. Initially, the kidneys respond by increasing urinary excretion and decreasing tubular resorption. However, tubular transport mechanisms eventually become saturated, leading to increasing serum phosphorus levels. Acute renal insufficiency caused by uric acid or other complications may further exacerbate the development of hyperphosphatemia. In 2008, a group of researchers published evidence-based guidelines for the prevention and treatment of tumor lysis syndrome.[116]

Management

Vigorous IV hydration with diuresis has long been the cornerstone to prevention and treatment of tumor lysis syndrome (to achieve urine output of 80 to 100 $mL/m^2/h$). Increasing intravascular volume and urine output increases the renal

excretion of uric acid and phosphate. Alkalinization of the urine is no longer recommended, due to the lack of supporting evidence and the potential for enhancing the precipitation of xanthine in the urine.[117] Allopurinol works to lower serum uric acid levels by reducing the production of uric acid from purine precursors by inhibiting xanthine oxidase. Because it does not alter the uric acid already formed, it works best when initiated at least 48 hours prior to chemotherapy.[117] It is generally well tolerated and can be given orally or intravenously; the dose needs adjustment for preexisting renal impairment.

Rasburicase

Recombinant urate oxidase exerts its pharmacologic activity by enzymatic oxidation of uric acid into allantoin. It works rapidly, often dropping the uric acid level to less than normal within hours. Although contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency, it is overall well tolerated. The traditional recommended dosage is 0.15 to 0.20 mg/kg per dose IV daily for up to 7 days. Investigators recommend the use of rasburicase as the first line intervention for high-risk patients (see Box 75.1) and as backup therapy for moderate-risk therapy for those patients who go on to develop hyperuricemia despite allopurinol and hydration (Table 75.2).[116]

TABLE 75.2

Patient Stratification by Risk

RISK

Data from Coiffier BJ. Guidelines for the management of pediatric and adult tumor lysis syndrome: an evidence-based review. Clin Oncol. 2008;26:2767-2778.

Work by Hobbs and associates showed partial reversal of AKI associated with elevated uric acid when treated with rasburicase in infants.[119] Rasburicase is remarkably well tolerated. The rare, but serious, adverse events that require prompt and permanent discontinuation of rasburicase are methemoglobinemia and hemolysis. Glucose-6-phosphate dehydrogenase (G6PD) deficiency is regarded as the main predisposing factor for hemolysis and remains a contraindication to its use (the mechanism is related to oxidative stress from the hydrogen peroxide [H_2O_2] produced as uric acid is converted to allantoin), justifying, when possible, the screening for patients at high risk for G6PD deficiency (eg, African or Mediterranean ancestry).

Role of Renal Replacement Therapy

The understanding of the optimal start time, method, and dosage of renal replacement therapies (RRTs) has evolved (see also Chapter 78). Early intervention is favored, because most AKI survivors leave the hospital with independent kidney function.[120] Once the process of cell turnover is uncoupled, the rapid release of intracellular contents into the bloodstream, including anions, cations, proteins, and nucleic acids, occurs. In this clinical paradigm, the early institution of renal replacement interrupts the cascade before the occurrence of tumor lysis–related AKI with life-threatening complications. Therefore, the group recommended that for pediatric patients at high risk of TLS, cytotoxic chemotherapy should only be administered in a facility with ready access to dialysis. Although dialysis usage has been reduced since the introduction of rasburicase, as many as 3% of patients (1.5% of pediatric patients and 5% of adult patients) still require RRT.[121] In line with this observation, the panel recommended that renal consultation be obtained immediately if urine output is low, if there are persistently elevated phosphate levels, or in the case of hypocalcemia.[116]

Pigment Nephropathy

Rhabdomyolysis is a dissolution of skeletal muscles that produces a nonspecific clinical syndrome that causes extrusion of toxic intracellular contents from myocytes into the circulatory system. The possible causes of rhabdomyolysis are myriad; with direct muscle injury remaining the most common cause, additional causes include hereditary enzyme disorders, drugs, toxins, endocrinopathies, malignant hyperthermia, neuroleptic malignant syndrome, heatstroke, hypothermia, electrolyte alterations, diabetic ketoacidosis and nonketotic hyperosmolar coma, severe hypothyroidism or hyperthyroidism, and bacterial or viral infections. Most of the data remain adult based. In a study of 210 pediatric patients, the most common causes of rhabdomyolysis were viral myositis (38%), trauma (26%), and connective tissue disease (5%). Higher initial creatine kinase levels (>6000 IU/dL) and higher fluid administration rates were associated with higher maximal creatinine levels.[122]

Pathophysiology

Rhabdomyolysis, which literally means "dissolution of striped [skeletal] muscle," is the final pathway of many different processes. Regardless of the underlying mechanism, myocyte dissolution triggers a cascade of events that leads to the rapid release of calcium ions into muscle cells resulting in a pathologic interaction between actin and myosin and activation of cell protease, with subsequent myocyte necrosis of muscle fibers, release of potassium, phosphates, myoglobin, creatine kinase (CK), and urates into the extracellular space and into the bloodstream. As such, myoglobin can precipitate in the glomerular filtrate, particularly in an acidic environment, causing tubular occlusion and severe kidney damage. Pigmented myoglobin casts, which characterize the rhabdomyolysis syndrome, are the result of the interaction between myoglobin and Tamm-Horsfall protein in an acid environment.[123] Additional mechanisms causing renal damage include (1) a direct cytotoxic effect of myoglobin on renal cells; (2) urate precipitation, leading to intraluminal casts, increased intratubular pressure, and subsequent decreased glomerular filtration rate; (3) renal vasoconstriction and ischemia due to the heme group of myoglobin causing

activation of the cytokine cascade; and (4) oxidant injury through heme-induced reactive oxygen species such as superoxide anion, hydrogen peroxide, or hydroxyl radicals causing direct oxidative damage.[124]

The classic triad of symptoms of rhabdomyolysis includes myalgia, weakness, and dark urine, although these findings may be inconsistent.[122]

The definitive diagnosis of rhabdomyolysis requires an elevation of CK levels to greater than five times normal in the absence of significant elevations of brain or cardiac CK fractions. The most dangerous sequela of rhabdomyolysis is AKI, the exact mechanisms of which are unclear but may be attributable to vasoconstriction/hypoperfusion, renal tubular dysfunction/cast formation, or myoglobin-induced tubular cytotoxicity.

The mainstay of treatment for rhabdomyolysis, directed at preventing AKI, is fluid therapy.[122] Many clinicians advocate alkalinization of urine with sodium bicarbonate (sometimes with concomitant forced diuresis with mannitol). Once the patient has reached the hospital, fluid infusion should be continued, with the goal of maintaining a brisk urinary flow and a urine pH above 6.5 and plasma pH below 7.50.[125] The rate of infusion should be at 150% of maintenance rate, with hemodynamic parameters and urine output monitored closely. Some authors also suggest administering mannitol. This is done to induce osmotic diuresis and to remove liquids from the damaged muscular interstitium, thus relaxing the compartments involved.[126] To force diuresis, some clinicians also recommend the addition of furosemide.

There is little clinical evidence to support the use of bicarbonate, mannitol, and furosemide. It is important to understand that the treatment benchmark is aggressive forced hydration with saline and glucose solutions. Studies in humans show that alkalinization and osmotic and diuretic treatment add little to the beneficial effect of hydration.[123] Forced hydration should be continued until the disappearance of myoglobinuria, which typically occurs after the third day. Hyperkalemia must be managed using the usual techniques, considering that treatment with glucose and insulin may prove to be ineffective in this context due to the damaged muscle's inability to capture potassium from the extracellular space. It is often necessary to treat severe hyperkalemia with renal replacement therapy.

Hypocalcemia

Secondary sequestration of calcium into damaged muscle cells must be viewed critically. Administration of intravenous calcium (either chloride or gluconate) should be used only to treat life-threatening electrocardiographic alterations, secondary to hyperkalemia or extreme hypocalcemia.

Drug-Induced Nephrotoxicity

Many different drugs and agents may cause AKI in children. In the ICU, factors such as age, pharmacogenetics, underlying disease, the dosage of the toxin, and concomitant medication all interact and influence the severity of nephrotoxic insults. Pediatric retrospective studies have reported incidences of AKI in PICUs of between 8% and 30%.[127] It is widely recognized that neonates have higher rates of AKI, especially following cardiac surgery, severe asphyxia, or premature birth. Although in most cases the etiology of AKI in the ICU is multifactorial (eg, sepsis,

ischemia/hypoperfusion), several large epidemiologic studies have shown that nephrotoxic drugs were contributing factors in 19% to 25% of cases of severe acute renal failure in critically ill adult patients.[128]

NSAIDs, antibiotics, amphotericin B, antiviral agents, angiotensin-converting enzyme (ACE) inhibitors, calcineurin inhibitors, radiocontrast media, and cytostatics are the most important drugs implicated in the etiology of AKI in children. The mechanisms of nephrotoxicity include constriction of intrarenal vessels, acute tubular necrosis, acute interstitial nephritis, and, more infrequently, tubular obstruction.[127]

Aminoglycoside Nephrotoxicity

Aminoglycosides (AGs) are non–protein-bound drugs that are primarily excreted unmetabolized by glomerular filtration. Their cationic nature facilitates binding to the tubuloepithelial membrane in the proximal tubule, resulting in rapid intracellular transport.[129] The molecular number of cationic groups determines the facility with which these drugs are transported across cell membranes and is an important determinant of toxicity.[130,131] Neomycin is associated with the most nephrotoxicity; gentamicin, tobramycin, and amikacin are intermediate, and streptomycin is the least nephrotoxic.[132] Several hypotheses have been proposed to explain the nephrotoxic effects of aminoglycosides. Intracellular accumulation of AG within lysosomes is thought to interfere with normal cellular function such as protein synthesis and mitochondrial function, eventually leading to cell death.[133] Aminoglycosides also are known to stimulate the calcium-sensing receptor on the apical membrane thereby inducing cell signaling and eventual cell death.[134]

Risk factors for aminoglycoside nephrotoxicity include the type of AG, high peak serum levels, cumulative dose, the duration and frequency of administration, and patient-related factors such as age, preexisting renal dysfunction, hypoalbuminemia, liver dysfunction, decreased renal perfusion, and the concomitant use of nephrotoxic drugs.[132]

Several approaches have been evaluated in both animals and humans as potential treatments to attenuate the nephrotoxicity of aminoglycosides. Investigators have demonstrated that calcium supplementation reduces the nephrotoxic effect, likely through competitive inhibition of calcium channels in the proximal tubule.[135] Similarly, calcium channel blockers also have been shown to attenuate AG nephrotoxicity.[136] Also the protective effect of concomitant use of β-lactam antibiotics has been recognized for several years, although the mechanism by which this may occur is somewhat unclear.[137,138] More recent investigations have evaluated a possible role for antioxidants in renoprotection.[139] Once-daily dosing of aminoglycosides is the only clinical approach that is commonly used to reduce nephrotoxicity.[140] The rationale for the efficacy of consolidated AG dosing against gram-negative bacteria is based on two pharmacodynamic properties of aminoglycosides: (1) the bacteriocidal mechanism of action is concentration-dependent and (2) there is a prolonged post-antibiotic effect.[132]

Clinical evidence of AG-induced acute tubular necrosis is seen within a week of initiation of aminoglycoside treatment. AG-induced acute renal failure is generally nonoliguric and may be associated with decreased urine concentrating ability and urinary magnesium wasting. It is generally reversible after discontinuation of the drug; however, supportive renal replacement therapy may be required. Alternative

antimicrobials may be considered when possible in patients at high risk for AG nephrotoxicity. If required and consolidated AG dosing is used, renal function should be assessed daily to monitor for changes in renal function, and trough levels should be followed to guide dosage.

Amphotericin B

The use of antifungals has become more commonplace in intensive care units, as the prevalence of fungemia (specifically candidemia) has increased in critically ill patients. For decades, amphotericin B was the drug of choice because of its broad spectrum of activity and its wide availability; however, its use has been sharply curtailed because of its considerable side effects (specifically, nephrotoxicity) and the availability of newer, less-toxic agents.

Approximately 80% of patients who receive treatment with amphotericin B will experience some renal dysfunction.[141] There are several mechanisms by which amphotericin B is thought to induce renal dysfunction: (1) by directly binding to tubular epithelial cells in the cortical collecting duct, resulting in altered cell permeability; (2) by causing sodium, potassium, and magnesium wasting; and (3) by directly causing afferent arteriolar (preglomerular) vasoconstriction.[142] Risk factors for amphotericin B nephrotoxicity include preexisting renal insufficiency, hypokalemia, volume depletion, the use of concomitant nephrotoxins, and large individual and cumulative dosages.[143]

A number of strategies have been studied to minimize the associated nephrotoxicity, including sodium loading and longer infusion rates.[144] Although some have shown a reduction in nephrotoxicity, these studies are very small and typically enroll low-risk patients. Lipid-based formulations of amphotericin B also are available, which may produce less nephrotoxicity. However, these agents are considerably more expensive. The introduction of alternative antifungal agents such as itraconazole, voriconazole, and caspofungin has largely supplanted the use of amphotericin B in high-risk patients with renal impairment; however, it continues to be used widely in patients with normal renal function because of its relatively low cost and broad spectrum of activity.

Given the presence of many underlying risk factors for nephrotoxicity in critically ill patients, it is recommended that amphotericin B should be avoided in this patient population if alternative therapies are available. When it is used, sodium loading with intravenous hydration is recommended to attenuate vasoconstrictive effects, and longer infusion times should also be considered. Renal function and serum electrolytes (specifically potassium) should be monitored during treatment.

Vancomycin

The use of vancomycin hydrochloride has increased considerably as it has become the standard therapy for treatment of methicillin-resistant *Staphylococcus aureus* infections. Data from the 2004 Centers for Disease Control and Prevention, National Nosocomial Infections Surveillance System indicate that the prevalence of methicillin-resistant *S. aureus* exceeds 50% in US hospitals. The synergistic nephrotoxicity of combination therapy involving vancomycin and aminoglycosides is well established, with a reported frequency of acute renal failure in the range of 20% to 30%. However, the nephrotoxicity of vancomycin alone increasingly is being

recognized as high-dose therapy has become more common for the treatment of methicillin-resistant *S. aureus*.[146] In addition, adult studies showed administration of vancomycin plus piperacillin-tazobactam may lead to higher rates of AKI.[147] An analysis by our group had similar findings in children: The incidence of AKI when vancomycin and piperacillin-tazobactam were administered together was fourfold greater compared to either medication alone (unpublished data).

Vancomycin is excreted by glomerular filtration, 80% to 90% in an unaltered form.[148] It is hard to determine the exact rates of vancomycin-related toxicity because most reported cases have had additional risk factors for acute renal failure, which makes it difficult to determine the true risk of treatment. The mechanism by which it exerts its nephrotoxicity is unknown. Independent risk factors for nephrotoxicity include the use of concomitant nephrotoxic agents, age, duration of therapy, and drug levels achieved.[147] Trough levels higher than 15 μg/mL are associated with increased risk of nephrotoxicity, and peak levels also have been associated with increased nephrotoxicity. The dosing of vancomycin requires careful consideration of renal function and estimated glomerular filtration rate. Trough levels should be monitored frequently in patients with fluctuating renal function.

Calcineurin Inhibitors

The introduction of calcineurin inhibitors (CNIs) for transplant recipients has led to dramatic improvement in both allograft and patient survival. The clinical use of CNIs often is limited by their nephrotoxic effect, which can present as two distinct and well-characterized forms: acute and chronic nephrotoxicity. Calcineurin inhibitor-induced AKI may occur as early as a few weeks or months after initiation of therapy. The clinical manifestations of CNI-induced renal dysfunction include reduction of GFR, hyperkalemia, hypertension, renal tubular acidosis, increased resorption of sodium, and oliguria. The acute adverse effects of calcineurin inhibitors on renal hemodynamics are thought to be directly related to the cyclosporine (CsA) or tacrolimus dosage and blood concentration and can be managed by dose reduction. This is in contrast to calcineurin inhibitor-induced chronic nephropathy, which is largely irreversible and can occur independently of acute renal dysfunction, CNI dosage, or blood concentration.

Although the exact mechanism of nephrotoxicity is not fully understood, several factors have been implicated in the pathogenesis of CNI nephrotoxicity.[149] Experimental models of acute CsA toxicity revealed that CsA administration is associated with afferent and efferent arteriolar vasoconstriction, which results in a significant reduction of renal plasma flow and GFR.[150,151] The precise mechanism by which CsA induces renal vasoconstriction has not been established clearly. Results from several studies indicate that vascular dysfunction induced by CsA results from an increase in vasoconstrictor factors that include endothelin, thromboxane, and angiotensin II, as well as a reduction of vasodilator factors such as prostacyclin and nitric oxide.[151,152]

Cyclosporine and tacrolimus differ with respect to side effects; however, the available data comparing nephrotoxicity are conflicting. Whereas some studies have suggested that tacrolimus may be associated with a decreased severity of renal dysfunction in comparison to CsA,[132] other investigators have demonstrated no difference between the two CNIs.[153]

Studies have been conflicting on the protective effect of calcium channel blockers

on the preservation of renal function for patients receiving CNIs. In a multicenter, prospective, randomized, placebo-controlled study in 118 cadaveric renal transplant recipients receiving CsA, the use of a calcium channel blocker resulted in a significantly better allograft function at 2 years and demonstrated an improvement in graft function, as assessed by serum creatinine and GFR, that was independent of lowered blood pressure.[154] More research is being done with goals of improving the safety profile of CNIs and identifying safer alternatives.

Sirolimus

Sirolimus is a mammalian target of rapamycin (mTOR) inhibitor that is becoming increasingly used in allograft preservation. Its target protein, mTOR, is a serine/threonine protein kinase that regulates cell growth, cell proliferation, cell motility, cell survival, protein synthesis, and transcription in transplantation.[155] As its use in transplant medicine is increasing, it was hoped that its lack of nephrotoxicity in animal models would be translated in humans to improve immunosuppression with minimal effect on renal function. Unfortunately, several studies suggest that sirolimus has inherent nephrotoxicity, such as the development of proteinuria and a delay in recovery from ischemia-reperfusion injury. In addition, several studies have shown that the nephrotoxicity associated with CNIs is exacerbated when used in combination with sirolimus.[156]

Nonsteroidal Antiinflammatory Drugs

In most circumstances, nonsteroidal antiinflammatory drugs (NSAIDs) do not pose a significant risk to patients with normal renal function. However, in situations in which renal perfusion is compromised (which is relatively common with critically ill patients), the inhibition of prostaglandin-induced vasodilation with the use of NSAIDs may further compromise renal blood flow and exacerbate ischemia. The renal effects of NSAIDs do seem to be dependent on the type, dose, and duration of treatment. Indomethacin is thought to be the most likely drug to impair renal function, and aspirin the least likely.[157] Patients at high risk of NSAID-induced nephrotoxicity include patients with preexisting renal dysfunction, those with severe cardiovascular or hepatic failure, or the concomitant use of other potentially nephrotoxic medications, such as aminoglycosides, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers.[157]

Contrast-Induced Nephropathy

Contrast-induced nephropathy (CIN) acute kidney injury is an important complication in the use of iodinated contrast media that accounts for a significant number of cases of hospital-acquired AKI. The occurrence of AKI as a result of contrast will continue to increase, as there is growing use of imaging and interventional procedures in pediatric intensive care patients.[158] At the same time, many patients in intensive and critical care units have compromised renal function, representing the most important risk factor for contrast-induced AKI.

Three core elements are intertwined in the pathophysiology of CIN: (1) direct toxicity of iodinated contrast to nephrons, (2) microshowers of atheroemboli to the kidneys, and (3) contrast- and atheroemboli-induced intrarenal vasoconstriction.[159] Direct toxicity to nephrons with iodinated contrast has been demonstrated and

seems to be related to the osmolality of the contrast.[160] Hence, low-ionic or nonionic, and low-osmolar or iso-osmolar contrast agents were shown to be less nephrotoxic in vitro. Microshowers of cholesterol emboli are believed to occur in up to 50% of percutaneous interventions where a guiding catheter is passed through the aorta. Most of these showers are clinically silent; however, in approximately 1% of high-risk cases, acute cholesterol emboli syndrome (CES) can develop, which is manifested by AKI, mesenteric ischemia, decreased microcirculation to the extremities, and, in some cases, embolic stroke.[161] Finally, intrarenal vasoconstriction as a pathologic vascular response to contrast media, and perhaps an organ response to cholesterol emboli, is a final hypoxic/ischemic injury to the kidney.[162] Hypoxia triggers activation of the renal sympathetic nervous system and results in a reduction in renal blood flow, especially in the outer medulla.[161] There is disagreement about the direct vasoconstrictor or vasodilator effects in the kidney of contrast agents when given to animals.[163] It is likely that in completely normal human renal blood vessels, contrast agents provoke a vasodilation and an osmotic diuresis. When there is vascular disease, endothelial dysfunction, and glomerular injury, however, contrast and the multifactorial insult of renal hypoxia provoke a vasoconstrictive response and hence mediate, in part, an ischemic injury.[163] The most important predictor of CIN is underlying renal dysfunction. The “remnant nephron” theory postulates that after sufficient chronic kidney damage has occurred, the remaining nephrons assume the remaining filtration load, require increased oxygen demands, and are more susceptible to ischemic and oxidative injury. Understanding the pathophysiology of CIN is key to devising a preventive strategy.

Role of Renal Replacement Therapy

Contrast media are removed by dialysis, but there is no clinical evidence that prophylactic dialysis reduces the risk of AKI, even when carried out within 1 hour or simultaneously with administration. Hemofiltration performed before and after contrast administration deserves further investigation given reports of reduced mortality and need for hemodialysis, but the high cost and need for prolonged ICU care will also limit the utility of this prophylactic approach.[164]

There are no currently approved pharmacologic agents that will prevent CIN AKI. With iodinated contrast, the pharmacologic agents tested in small trials that deserve further evaluation include theophylline, statins, ascorbic acid, and prostaglandin E_1.[165] Although popular, *N*-acetylcysteine has not been consistently shown to be effective. Nine published meta-analyses document significant heterogeneity between studies and pooled odds ratios for *N*-acetylcysteine approaching unity.[166] Importantly, only in those trials in which *N*-acetylcysteine reduced serum creatinine below baseline values because of decreased skeletal muscle production did renal injury rates seem to be reduced. Thus *N*-acetylcysteine seems to falsely lower creatinine and not fundamentally protect the kidney against injury. However, a study suggested that the use of volume supplementation with sodium bicarbonate together with *N*-acetylcysteine was more effective than *N*-acetylcysteine alone in reducing the risk of CIN. Fenoldopam, dopamine, calcium channel blockers, atrial natriuretic peptide, and L-arginine have not been shown to be effective in the prevention of contrast-induced AKI. Furosemide, mannitol, and an endothelin-receptor antagonist are potentially detrimental.[166]

Acute Renal Failure After Stem Cell Transplantation

One of the most frequent complications of bone marrow transplant (BMT) is renal failure, with 5% to 15% of all BMT patients developing AKI and 5% to 20% of the survivors developing chronic renal failure (CRF).[167] Hematopoietic stem cell transplantation is a common procedure for the treatment of malignancies and some nonmalignant hematologic disorders. The process of stem cell transfusion predisposes these patients to renal failure because of prior chemotherapy, irradiation, sepsis, and exposure to nephrotoxic agents. Complicating outcomes are newer conditioning regimens that allow for reduced intensity and nonmyeloablative regimens, thereby allowing patients with significant comorbidities to undergo transplantation with reduced morbidity and mortality. These have led to challenges in the ICU management of these patients, because they already have residual organ injury. A study of 29 pediatric patients who required continuous renal replacement therapy (CRRT) in the ICU showed an almost 100% mortality at 6 months post-ICU admission due to transplant-related illness. This study demonstrated the management and ethical difficulties being posed by hematopoietic stem cell transplant patients becoming critically ill and requiring organ support at tertiary care centers. In contrast with the improving survival rates following stem cell transplantation, there are greater numbers of children surviving and progressing to end-stage renal disease (ESRD). Some of these patients are being treated with renal transplantation.[168]

A better understanding of the underlying histopathologic changes in renal morphology would perhaps lead to a better control of the renal insults that occur during the process of stem cell transfusion. Some histopathology-based studies have shown a variety of findings in patients post–stem cell transplantation, including features of tubulitis and peritubular vasculitis. These studies also show that kidneys from adult patients who had grade III-IV graft-versus-host disease (GVHD) were more likely to have tubulitis and peritubular capillaritis.[169] Other studies have shown membranous glomerulonephritis and thrombotic microangiopathy to be common histologic features post–stem cell transplantation.[170] However, there remains a paucity of pediatric studies examining renal histopathology in patients posttransplantation (see also Chapter 95).

Urinary Tract Obstruction

Obstruction of urine flow may result in AKI, although unilateral obstruction rarely causes AKI unless there is a single kidney or disease in the other kidney. Both unilateral and bilateral ureteral obstructions are accompanied by an initial increase in RBF caused by afferent arteriolar vasodilation.[171] Relaxation of the preglomerular capillary sphincter is mediated by the local release of vasodilatory prostaglandins.[172] Administration of indomethacin, a cyclooxygenase inhibitor, results in a marked reduction in the GFR after a decrease in glomerular plasma flow and an increase in both afferent and efferent arteriolar resistances.[173] This indicates an important role of vasodilatory prostaglandins in the maintenance of the GFR.

If the obstruction persists, RBF progressively decreases as afferent arteriolar resistance increases because of the overriding action of angiotensin II and thromboxane. This vasoconstriction may actually protect the kidney from damage during the period of obstruction. Intratubular pressure rises after ureteral

obstruction; this pressure is translated to the glomerulus as increased pressure in the Bowman space. The contribution of this increased force opposing filtration to the decrease in the GFR is probably inconsequential because the intratubular pressure rise is transient.[171] In addition, the elevation in Bowman space pressure is negated by an increase in the glomerular capillary pressure that increases the GFR. RBF is redistributed from the outer to the inner cortex and results in relative ischemia of the kidney medulla.[171]

Various clinical causes of urinary tract obstruction are listed in Table 75.3. The most important factors determining recovery of kidney and tubular function are the degree and severity of the obstruction. Treatment consists of decompression of the urinary collecting system by removal of the obstruction or by urinary diversion. Relief of obstruction is accompanied by a marked diuresis resulting from increased RBF and abnormal tubular function. The increase in urine volume is related to a concentrating defect caused by loss of the medullary gradient and unresponsiveness of the kidney tubule to vasopressin.[174] Hydrogen ion and potassium secretion may also be impaired, and the result is a distal type of kidney tubular acidosis with hyperkalemia.[175]

TABLE 75.3

Management of Electrolyte Abnormalities

Abnormality	**Management Recommendation**
Hyperphosphatemia	
Moderate (≥2.1 mmol/L)	Avoid IV phosphate administration Administration of phosphate binder
Severe	Dialysis, CAVH, CVVH, CAVHD, or CVVHD
Hypocalcemia (≤1.75 mmol/L)	
Asymptomatic	No therapy
Symptomatic	Calcium gluconate 50-100 mg/kg IV administered slowly with ECG monitoring
Hyperkalemia	
Moderate and asymptomatic (≥6 mmol/L)	Avoid IV and oral potassium ECG and cardiac rhythm monitoring Sodium polystyrene sulfonate
Severe (>7 mmol/L) or symptomatic	Same as above, plus: Calcium gluconate 100-200 mg/kg by slow IV infusion for life-threatening arrhythmias Regular insulin (0.1 U/kg IV) + D25 (2 mL/kg) IV Sodium bicarbonate (1-2 mEq/kg IV push) can be given to induce influx of potassium into cells; however, sodium bicarbonate and calcium should not be administered through the same line Dialysis
Renal dysfunction (uremia)	Fluid and electrolyte management Uric acid and phosphate management Adjust renally excreted drug doses Dialysis (hemodialysis or peritoneal) Hemofiltration (CAVH, CVVH, CAVHD, or CVVHD)

CAVH, continuous arteriovenous hemofiltration; *CAVHD*, continuous arteriovenous hemodialysis; *CVVH*, continuous venovenous hemofiltration; *CVVHD*, continuous venovenous hemodialysis.

Conclusions

This chapter has reviewed the major factors that contribute to the development of AKI, both in its oliguric and nonoliguric forms. Also indicated are the clinical

settings in which AKI may occur. In addition, treatment modalities have been discussed. Clearly, the challenge in AKI is the development of novel therapeutic strategies that will more directly intervene in the disease process and that can have an impact on the cellular and metabolic mechanisms that contribute to kidney cell injury. Certain current investigations were discussed because they may lead to clinical trials in the coming years. Included among these agents are calcium channel blockers, adenine nucleotides, thyroid hormone, and oxyradical scavengers because they may modulate the full expression of kidney cell injury. Only with an understanding of the pathophysiologic mechanisms in AKI can these potential therapeutics be applied in a clinical setting to the care of pediatric patients.

CHAPTER 76

Acid-Base Disorders

Hector Carrillo-Lopez, Adrian Chavez, Alberto Jarillo

PEARLS

- Plasma and intracellular fluid can be viewed as a complex aqueous solution with multiple cations and anions that interact with each other and with the solvent, water. Until recently, water was viewed as a passive element in the acid-base balance, but it is now envisioned as a physicochemical active participant, because it represents a virtually inexhaustible source of hydrogen ions.
- The principles of electroneutrality, constancy of the ionic product for water, and the law of mass action all influence acid-base equilibrium.
- PCO_2, pH, standard base excess, and HCO_3^-, with the addition of anion gap, are the tools used in a classical acid-base assessment.
- According to the physicochemical approach to acid-base balance, PCO_2 and the balance between cations and anions are the main determinants of pH, through water dissociation and regulatory responses of lung ventilation and the kidneys.
- Because PCO_2 is regulated by ventilation, changes in PCO_2 result in respiratory acid-base disorders, in both the classical and physicochemical acid-base models, but in the latter HCO_3^- is considered as primarily determined by PCO_2 and not vice versa.
- *Strong ion* (fully dissociated) *difference (SID)* and plasma nonbicarbonate (nonvolatile) weak acids (A_{TOT}) are the determinants of metabolic acid-base balance.
- The apparent gap between the sum of all strong cations and all the strong anions is called *apparent strong ion difference (SID_{APP})*, which is calculated as ($[Na^+] + [K^+] + [Ca^{2+}] + [Mg^{2+}]$) − ($[Cl^-]$+ [lactate$^-$]). The difference between $[Na^+]$ and $[Cl^-]$ is an effective surrogate of the more cumbersome calculation of SID_{APP}.
- According to the principle of electroneutrality, there must be remaining negative charges balancing the *excess* of plasma strong cations in relation to the strong anions. These balancing negative charges come from weak anions or acids that include total CO_2 (~$[HCO_3^-]$), albumin, and dihydrogen phosphate. Once weak acids are quantitatively taken into account, the SID_{APP} to SID_{EFF} difference should equal zero (electrical charge neutrality) unless there are unmeasured charges to explain this *ion gap.*
- Clinical assessment of an acid-base disorder should utilize all the tools of the

classical approach, in addition to some merging concepts from the physicochemical approach. Anion gap must always be *corrected* for albumin and lactate levels in order to surrogate SIG, and the sodium-chloride difference can be used to surrogate SID_{APP}. These two indexes are particularly important in the setting of high-volume resuscitation, if the presence of unmeasured anions is expected, or if a complex or mixed pattern of acid-base metabolic derangement is suspected.

- Among all metabolic acidoses, lactic acidosis signals trouble.
- Acid-base disorders must be considered more important for what they tell the clinician about the patient than for any harm that is directly provoked by the acid-base imbalance. Mortality is more closely related to the nature of an acid-base disorder than to the magnitude of the derangement of the pH, whether acidotic or alkalotic.

Acid-base disorders are common in the critically ill of every age.[1] Acid-base homeostasis remains one of the best examples of the close correlation between basic and clinical sciences. To master acid balance physiology and pathophysiology is not an easy task, because it is patently integrative.[2-5] This implies that understanding the data in a blood gas panel requires an appreciation of not only acids and bases but also ventilation, gas exchange, dynamics of electrolyte and water movement, plasma composition, hemodynamics, respiratory control, and renal mechanisms of hydrogen ions, electrolytes, and water excretion. In addition, it is essential to have an understanding of a number of other organic, metabolic, and structural dysfunctions that can potentially contribute to deficits or loads of acid or base in the extracellular or intracellular spaces, including sepsis, acute kidney injury, different types of shock and tissue damage, severe metabolic dysregulation (eg, inborn errors, diabetic ketoacidosis), and the toxic effects of certain compounds and medications. Thus it is not uncommon that many physicians seem to display only a superficial knowledge of this field.[5-8] Although most of the acid-base unbalances do not cause harm and are self-limiting after appropriate resuscitation and management of the associated clinical condition, many physicians and critical care practitioners tend to think about an acid-base disturbance as a disease, and they unfortunately spend long hours treating numbers rather than the patient. This response probably relates to the fact that traditional teaching emphasizes data interpretation rather than pathophysiology. Thus a sizable number of critical care physicians experience difficulty in interpreting the significance or understanding of various acid-base disturbances.[6-9] Hence it is not a surprise to find easily available software for computers, handheld devices and smartphone applications, along with Internet-available blood-gas calculators, videos, tutorials, and primers for the interpretation of blood gases and acid-base status, with a variable level of quality and accuracy.[9-17] This is because some clinicians lack a logical stepwise learning approach or they are not organized to maximize ease of learning.[18] Numerous so-called practical solutions for understanding the acid-base physiology and its clinical implications seem to imply that many health workers, physicians included, seem to need some assistance to truly master the acid-base balance and its derangements. As a paradox, it is likely that such quick solutions contribute to the situation, as they provide practitioners

with a fast-track interpretation of the arterial and venous blood gases and acid-base status, even when all the complexities are not fully understand.[2-8]

Because intensivists spend much of their time managing problems related to fluids, electrolytes, and acid-base balance, a thorough but practical understanding of the physiology and pathophysiology of acid-base disorders is a central aspect of the expertise of critical care practitioners in both pediatric and adult fields.

Overview of Acid-Base Physiology

Defining Acids and Bases

Most of the concepts of acid-base physiology are founded on the accepted definitions of acids and bases. These definitions and understanding of acid-base physiology were profoundly transformed at the end of the 19th and in the early 20th centuries. Between 1887 and 1903 Svante Arrhenius outlined the theories of ionization and dissociation, and Ostwald described the ability of water to dissociate, generating hydrogen (H^+) and hydroxide or hydroxyl (OH^-) ions. Arrhenius defined an acid as any substance that, when dissolved in water, produces an increased concentration of hydrogen ions, H.[19-21] In this definition it is not mandatory for a given substance to have hydrogen atoms, as the water itself can be the source of the hydrogen ions, in agreement with the works from Ostwald.[20-21] Accordingly, an Arrhenius base is a substance that, when dissolved in water, decreases the concentration of H^+ ions.[19,22] Consequently, by 1900 Naunyn and others proposed that the acid-base status in biological systems was, at least partially, determined by the concentration of electrolytes, mainly sodium and chloride, which had been formerly described by Faraday as “base-forming cation” and “acid-forming anion,” respectively.[21] In 1923, Brönsted in Denmark and Lowry in England, working independently, stated that an acid is a substance that contains hydrogen atoms and that is able to release them—that is, an acid is a proton-donor substance.[21,22] Thus an acid (HA) may dissociate and donate a proton (ie, an hydrogen ion, H^+) to the solution, forming the conjugate base (or anion) A^- in a reversible manner, according to the law of mass action:

$$[HA] \xleftrightarrow{K_a} [H^+] + [A^-] \qquad \textbf{(Eq. 1)}$$

where K_a (or K_{eq}) is the equilibrium or dissociation constant, particular to every different substance and influenced by the characteristics of the particular solution in which the reaction is taking place. Therefore a base is a substance with the ability for binding or *trapping* free hydrogen ions (“proton acceptor substance”).[22-25] Examples include bicarbonate, hemoglobin, proteins, and phosphates. The Brønsted-Lowry definition led to the concept of conjugate acid-base pairs. Whatever definition of acid is used, its validity depends on the given situation in which one is trying to understand or explain some event. The broader definitions of acids and bases from Brønsted and Lowry and others were designed for chemistry, as they extend the concepts of acidity and alkalinity beyond the aqueous systems, to which the Arrhenius definitions are restricted.[22-26] In the context of the body fluids, the two definitions are not only valid but are both necessary to understand the complete picture in complex biological solutions. The Arrhenius definitions acknowledge the

paramount participation of chloride, sodium, and other strong (fully dissociated) ions, whereas Brønsted-Lowry's definition recognizes the importance of the conjugate acid-base pairs, such as the bicarbonate/carbonic acid system. In spite of the fact that some of the most important developments in the evolution of acid-base physiology occurred before the publication of the Brønsted-Lowry theory in 1923, this definition gradually became the most popular among acid-base physiologists, and the Arrhenius definitions became outdated, as many thought that this approach to acid-base balance did not include the central and direct role of hydrogen ions. However, with this approach, the concept of chloride as an acid-forming anion and sodium as a base-forming cation became obsolete.[21-24] It was argued that there was an insufficient link between electrolytes such as sodium and chloride and subsequent changes in hydrogen ions. However, the role of water as a hydrogen ion source was neglected.

Role of Water and Electrolytes in Acid-Base Balance

All body fluids are water-based solutions. It seems rather surprising to find that water was rendered as a passive component of the body fluids until somewhat recent times.[26-28] From the work of Arrhenius and Ostwald, it is now well known that water molecules exhibit self-ionization or auto-dissociation. The hydrogen ion, H^+, immediately protonates another water molecule to form the so-called hydronium ion, H_3O^+ (also known as hydroxonium ion or oxonium ion):

$$H_2O + H_2O \leftrightarrow H_3O^+ + OH^- \quad \textbf{(Eq. 2A)}$$

This equilibrium applies both to pure water and to any aqueous solution.

The symbol H^+ is interpreted as a shorthand for H_3O^+ because it is now known that a bare proton does not exist as a free species in aqueous solution. Accordingly, in medical biochemistry water dissociation is usually written as follows:

$$H_2O \leftrightarrow H^+ + OH^- \quad \textbf{(Eq. 2B)}$$

Because water can supply a virtually inexhaustible natural reservoir of hydrogen (and hydroxyl) ions, acid-base balance must include the chemical properties of water. Acid-base unbalance can be viewed as an alteration of water dissociation. Although pure water dissociates only slightly, in plasma the presence of electrolytes, CO_2, and other weak acids produces powerful electrochemical forces, influencing water dissociation.[29,30] Human plasma is an aqueous solution that has to comply with certain physicochemical laws and principles, such as the *principle of electrical neutrality*, the *law of mass action* (which explains the dissociation equilibrium of partially dissociated substances such as electrolytes and others), and the *constancy of the ionic product for water*. The state of ionization of plasma water varies according to the plasma ionic composition to maintain these chemical rules.[29-33]

Principle of Electroneutrality

In physiologic conditions, there is little dissociation of water molecules into its components (Eqs. 2A and 2B). Electrical charge and temperature represent the main determinants for its eventual dissociation. Electrolytes and other substances, mainly organic acids, dissociate in water, forming cations (positively charged ions) and anions (negatively charged ions). In humans, plasma cations include hydrogen ion (H^+), sodium, potassium, calcium, magnesium, and ammonium. Sodium ion contributes quantitatively the greatest positive charge to plasma, with a concentration of approximately 140 mEq/L or millimoles per liter (mmol/L, mM). Plasma anions include hydroxide ion (OH^-, also termed *hydroxyl ion*), chloride, bicarbonate (HCO_3^-), albumin, phosphate, lactate, β-hydroxybutyrate, acetoacetate, sulphate, urate, and other organic anions such as pyruvate and propionate. The most abundant anion in human plasma is chloride with a concentration of approximately 100 mEq/L or mmol/L, mM. The plasma bicarbonate level is approximately 25 mEq/L (or mmol/L, mM) and therefore also contributes significantly to the plasma negative charge in quantitative terms.

In aqueous solutions, electrical neutrality is always constant—that is, the sum of all positively charged ions (cations) must be equal to the sum of all negatively charged ions (anions). Both extra- and intracellular fluids are an ionic mix of electrolytes, proteins, and other substances, whose charges tend to modify the electrical balance and then can have an influence on the dissociation of water. To preserve normal plasma ionic composition and to keep electroneutrality, the kidneys produce urine with different concentration of ions depending on body requirements. Urine cations include sodium, potassium, calcium, magnesium, ammonium, and hydrogen ions. Urine anions include chloride, bicarbonate, phosphate, sulphate, citrate, oxalate, and hydroxide ions. Plasma and urine are electrically neutral and the sum of anions (negative electrical charge) equals the sum of cations (positive electrical charge).[29,30,33] So that electroneutrality can be maintained, water molecules dissociate. In other words, the determinants of $[H^+]$ are the determinants of water dissociation, and the quantification of the water dissociation is made through the measurement of the hydrogen ion concentration $[H^+]$.[29]

Normal concentration of hydrogen ions in the extracellular fluid is extremely low, in the nanoequivalent (nEq) or nanomole (nmol) range. The usual arterial blood $[H^+]$ is about 40 nEq/L (or nmol/L).[34] In other words, serum $[H^+]$ is about 3 million times less than the serum sodium concentration.[35] For convenience, the $[H^+]$ value is usually expressed as pH units, which are obtained from the negative $\log_{10}$ of the hydrogen ion concentration in nanoequivalents per liter. This concept was developed by Sörensen and adapted by Karl Hasselbalch into clinical medicine in 1909.[36,37] A normal pH of 7.4 corresponds to a blood hydrogen ion concentration of 40 nEq/L, at 37°C. The relationship between pH and serum $[H^+]$ is nonlinear, but it is almost linear over the narrow normal pH range of 7.35 to 7.45 (corresponding to 45 to 35 nEq/L of $[H^+]$).[35,37] When the hydrogen ion concentration increases, pH will decrease, and vice versa. Nevertheless, the logarithmic scale of pH can be somewhat confusing, because it has the negative effect of obscuring the magnitude of deviations from normal. For example, a change in pH from a normal value of 7.4 to 7.2, a decrease of *only* 0.2, results in a 60% increase in $[H^+]$ from 40 to 63 nEq/L or nmol/L.[29,37] Although the use of pH instead of nanomoles of H^+ has been repeatedly challenged, pH has survived, as pH provides a measurement of the *activity* of the H^+, rather than simple H^+concentration.[36-38]

The term *acidosis* is used to describe the process that tends to produce an increase in [H^+], whether or not there is a change in blood pH. *Alkalosis* is the opposite—that is, the process that tends to produce a decrease in [H^+], with or without changes in blood pH. *Acidemia* and *alkalemia* are the corresponding terms for those situations in which blood pH actually changes.[34,35]

Constancy of the Ionic Product for Water

Any reversible chemical reaction at a specific temperature has a specific equilibrium constant. The law of mass action, which defines the final equilibrium concentrations of reactants and products, can be applied to the water dissociation reaction (Eqs. 2A and 2B), and therefore an equilibrium constant (K_{eq} or K_a) for the reversible ionization of water can be defined[33,39,40]:

$$K_{eq} = \frac{[H^+][OH^-]}{[H_2O]} \quad \textbf{(Eq. 3)}$$

At any given time, the number of hydronium (hydrogen) ions and hydroxide ions present in water is extremely small and consequently the concentration of undissociated water molecules ([H_2O]) is virtually unchanged by this minute ionization and may be considered a constant:

$$K_{eq} \times [H_2O] = [H^+][OH^-] \quad \textbf{(Eq. 4)}$$

The product $K_{eq} \times [H_2O]$ is a constant termed the *ionic product for water (K_w)*, which therefore is expressed as follows:

$$K_w = [H^+][OH^-] \quad \textbf{(Eq. 5)}$$

The concentration of molecules in pure water is 55.5 M and the value for the equilibrium constant, determined by electrical conductivity measurements, is 1.8×10^{-16} M at 25°C of temperature. Substituting these values in the equilibrium constant equation (Eq. 5):

$$K_w = (1.8 \times 10^{-16}) \times 55.5 = 99.9 \times 10^{-16} \approx 1 \times 10^{-14} \quad \textbf{(Eq. 6)}$$

Therefore,

$$K_w = [H^+][OH^-] = 10^{-14,33,39,40} \quad \textbf{(Eq. 7)}$$

In pure water, the concentration of hydrogen ions is equal to the concentration of hydroxide ions: ([H^+] = [OH^-]). Hence at 25°C, both concentrations are equal to 10^{-7} M. The ionic product for water ([H^+][OH^-]) is always constant in any aqueous

solution, regardless of the presence of dissolved solutes.[33,40] If the presence of other electrically charged molecules provokes a change in the concentration of either hydrogen ions or hydroxide ions, a concomitant change of the same magnitude must occur in the other ion to maintain constant the ionic product for water.[30-33,39]

Variations in the concentration of plasma ions, either anions or cations, organic acids or electrolytes, may modify the relative proportion of anions and cations and predictably lead to a change in the plasma concentration of hydrogen ions by driving changes and adjustments in water ionization, thus allowing plasma electroneutrality while maintaining constant the ionic product for water.[30-33,39]

Acids, Bases, and Buffers

Clinical acid-base base balance includes a combination of the Arrhenius approach (acid = H^+ increased in aqueous solution) and the Brönsted-Lowry approach (acid = proton donor).[21,41] In a similar way, bases are compounds that decrease the concentration of hydrogen ions, either by accepting the protons directly in their own molecules or by decreasing $[H^+]$ as a result of the electrochemical effect of certain solutes on water dissociation. For instance, hydrochloric acid (HCl) dissociates into H^+ and chloride (Cl^-) when dissolved in water, whereas ammonia (NH_3) becomes protonated when dissolved in water producing ammonium ion (NH_4^+). Each acid or base, as proton donor or acceptor, has a characteristic tendency to release or to catch hydrogen ions in an aqueous solution, according to the reversible reaction depicted in Eq. 8.[1]

$$K_a = \frac{[H^+][A^-]}{[HA]} \qquad \textbf{(Eq. 8)}$$

The tendency of an acid to dissociate releasing hydrogen ions and anions may be assessed from equilibrium or dissociation constant (K_a). The larger the value of the equilibrium constant, the greater the tendency of the acid to dissociate and the stronger the acid. An acid is considered strong when it dissociates its hydrogen ion easily because the corresponding base has a low affinity for it (high K_a value). The relative strength of a base can be assessed in a similar way: The lower the value of its dissociation constant, the higher the tendency of the base to capture hydrogen ions (protons) and the higher the concentration of the protonated molecule.[22,23,33,42]

The dissociation constant K_a, as in the case of pH, can be expressed as $-\log_{10}K_a$ and is termed pK_a, which is the most used measure of the tendency of the acid-base pair to ionize. The well-known Henderson-Hasselbalch equation is the logarithmic transformation of the equilibrium constant equation, in which pH is the −log of [H+] and pK_a is the −log of Ka:

$$\mathrm{pH} = \mathrm{p}K_a + \log\frac{[A^-]}{[HA]} \quad \text{in the case of an acid} \qquad \textbf{(Eq. 9)}$$

or

$$\mathrm{pH} = \mathrm{p}K_a + \log \frac{[\mathrm{B}]}{[\mathrm{HB}^+]} \quad \text{in the case of a base} \qquad \textbf{(Eq. 10)}$$

The pK_a estimates the relative strength of an acid or base. Strong acids have a low pK_a (high K_a) and weak acids have high pK_a (low K_a). The tendency of a base to join hydrogen ions also is reflected in the pK_a value. The stronger the base, the greater its tendency to bind protons and the higher its pK_a (and lower the K_a).[33,42] When the concentration of the undissociated moiety of both acids and bases is equal to the concentration of the dissociated moiety, then pH equals pK_a as log 1 = 0. Therefore the pK_a of an acid or a base is the pH at which the concentration of dissociated and undissociated forms is the same, as can be understood with a quick view to Eqs. 9 and 10.

When the pK_a of an acid is lower than the pH of the aqueous solution in which it is dissolved, the acid tends to dissociate itself, at least in a certain proportion, and releases hydrogen ions, being transformed into an anion. Strong acids have low pK_a values, usually below 3, and completely dissociate in aqueous solutions, yielding strong anions. Such is the case of the pair constituted by phosphoric acid (H_3PO_4)/dihydrogen phosphate ($H_2PO_4^-$), with a pK_a of 1.97, which means that phosphoric acid is virtually not present in the human body but as its anion form $H_2PO_4^-$. Acids with pK_a values of around 4 or less also generate rather strong anions at physiologic pH values. Many organic acids existing in the human body have pK_a values around 4 and therefore appear predominantly in their anionic form, such as the pair carbonic acid/ bicarbonate (H_2CO_3/HCO_3^-) with pK_a = 3.7; lactic acid/lactate, pK_a= 3.86; pyruvic acid/pyruvate, pK_a = 2.49; citric acid/citrate, pK_a = 3.09; acetoacetic acid/acetoacetate, pK_a = 3.58; and β-hydroxybutyric acid/β-hydroxybutyrate, pK_a = 4.39.[33] When the pH of the aqueous solution is lower than the pK_a value of a dissolved base, the base captures hydrogen ions and becomes protonated. Strong bases have high pK_a values and therefore they remain protonated at physiologic plasma pH. For instance, the pK_a value for the pair NH_3/NH_4^+ is 9.3, indicating that virtually only the protonated moiety (NH_4^+) is present in the human body. Something similar occurs with the pair monohydrogen phosphate (HPO_4^{2-})/phosphate (PO_4^{3-}), which has a pK_a of 12.35.

Weak acids only partially dissociate because their corresponding base has high affinity for hydrogen ions (high pK_a, low K_a values). When this is the case, both the acid and base forms of the parental molecule are present in the resulting solution in near-equimolar proportions. Thus weak acids and bases are those with pK_a values closer to approximately 7. These solutions have the ability to resist changes in pH after the addition of a strong acid or base. This solution, constituted by an acid-base pair, was designed with the word *puffer* (in German), which was first introduced in the scientific lexicon in the first decade of the 20th century, and popularized as *buffer,* to refer to the property of weak acid-base pairs that tends to minimize changes in pH by reversibly *producing* or *consuming* hydrogen ions.[43]

An ideal buffer is a weak acid in equilibrium with its corresponding weak base. This weak acid-base pair is more effective as a buffer in living systems when its pK_a

is close to physiologic pH.[22,33,42,43] At physiologic pH values, their degree of dissociation or protonation, respectively, is variable. Weak anions in the human body include the pair dihydrogen phosphate/monohydrogen phosphate ($H_2PO_4^-/HPO_4^{2-}$), with a pK_a of 6.86, and uric acid/urate (pK_a 5.75).

Physiologic buffering systems may be classified into two general categories: the bicarbonate/carbonic acid (HCO_3^-/ H_2CO_3) buffering system, which acts in both the extracellular space and inside the erythrocytes, and the nonbicarbonate buffers, which include hemoglobin and oxyhemoglobin, organic phosphates, inorganic phosphates (in intracellular space), and plasma proteins. Extracellular buffers (HCO_3^-, plasma proteins) represent the body's first, more abundant and immediate line of defense against any alteration of pH of the body fluids. In the bicarbonate/carbonic acid (HCO_3^-/H_2CO_3) buffering system, the acid part is actually constituted by the sum of both the volatile [CO_2] and nonvolatile [H_2CO_3] forms of the carbonic acid, which is a moderately strong acid with a pK_a of 3.7. However, most of the acid moiety of the bicarbonate/carbonic acid buffering system is CO_2, with only about one-thousandth as the full H_2CO_3 molecule. Thus when [CO_2] is included in the dissociation equation (Eqs. 8-10), the pK_a shifts to 6.1, which is equivalent to a dissociation constant (K_a) about a thousand times smaller and much closer to the physiologic pH, which makes the [HCO_3^-]/[CO_2] system a powerful buffer.

After extracellular buffering occurs, a second intracellular phase takes place, as long as intracellular buffers (intracellular proteins, dibasic phosphates, hemoglobin-oxyhemoglobin, and carbonate in bones) reach buffering capacity over the next several hours.[43,44] The buffering systems (with the exception of HCO_3^-/CO_2) cannot truly eliminate hydrogen ions from the body, but they tamper sudden changes in [H^+] (or pH) and buy time until a new balance can be achieved. Altogether, extracellular and intracellular buffers provide a volume of distribution close to that of the total body water to any exogenous acid load (or deficit). This represents a formidable capacity for resisting changes in pH.

The major acid-base buffering system in the blood, the bicarbonate/carbonic acid system, has the tremendous advantage of its interconversion with CO_2, the volatile form of H_2CO_3, which means this is an *open system* buffer:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^- \qquad \textbf{(Eq. 11)}$$

Any increase in [H^+] (or drop in pH) will shift the preceding reaction to the left, including an increase in alveolar ventilation to eliminate the resultant increase in CO_2. This respiratory response begins within minutes, but it may not reach a steady state for 12 to 24 hours. This method of achieving a fast and actual decrease of the acid component is a unique characteristic of the bicarbonate/carbonic acid buffering system. For the other buffers, the addition or removal of hydrogen ions has the corresponding opposite effects on the buffer components, limiting the maximum buffering capacity. However, the capacity of the bicarbonate-CO_2 system is greatly increased because the lungs can eliminate a vast amount of CO_2 per day. Similarly,

the kidneys can eliminate or regenerate bicarbonate, as needed, although its response is slower than that of the lungs. This respiratory response is particularly useful to the tissues, because of its rapid effect on intracellular pH as well as extracellular pH. Carbon dioxide crosses cell membranes easily, so changes in PCO_2 affect intracellular pH rapidly and in a predictable direction.

Tight regulation of the H^+ is mandatory for the body, because nearly every metabolic pathway includes moieties such as phosphate, ammonium, or carboxylic acid, which undergo variable ionization with changes in pH.[38,41,43,45] The body has a relatively large capacity to tolerate severe shifts in the levels of pH. For example, from a pH of 7.4 (40 nEq/L or nmol/L) to a severe acidosis of pH 6.7 (equivalent to 175 nEq/L or nmol/L), the $[H^+]$ increases by a factor of 4, and this could not be tolerated with other ions such as potassium, calcium, or chloride.[41] Nevertheless, the range of pH compatible with life, of about 6.9 (0.126 mEq/L or mmol/l H^+) to 7.6 (0.025 mEq/L or mmol/L H+), implies a difference in $[H^+]$ of barely 0.1 mEq/L or mmol/L. It is amazing that an ion with such a low concentration plays such a major role in body homeostasis. Hydrogen ion concentration and, more important, hydrogen ion activity have a strong influence on the function of almost all enzymatic systems of the body.[41,43,45]

In the body, normal metabolism continuously produces both anions and cations, (ie, acids and bases) in two major ways. The first one involves CO_2 production during oxidative metabolism of carbohydrates, fat, and amino acids, which is then hydrated by the cytoplasmic and erythrocytic carbonic anhydrase to produce carbonic acid (H_2CO_3), which dissociates in hydrogen ion and bicarbonate (Eq. 11).

The second pathway involves cations such as ammonium and anions such as nonvolatile metabolic acids that are produced by the normal daily catabolic load (oxidation of sulfur [SO_4^{2-}] containing amino acids, hydrolysis of pyrophosphate, and orthophosphate esters) or during situations with incomplete catabolism of carbohydrates and fat, such as lactic acidosis or diabetic ketoacidosis (DKA), with increased acetoacetate and β-hydroxybutyrate, or in cases with defective processing or excretion of certain metabolites, as occurs in some inborn errors of metabolism and in uremic acidosis. The free hydrogen ions are neutralized by extracellular and intracellular buffers, but because these acids are not in equilibrium in the normal plasma, they must be metabolized, mainly in the liver, and then excreted by the kidneys.[43,44] In addition, other charged molecules circulate in human plasma, including anions such as albumin and cations such as immunoglobulins. Anomalous plasma ions may be derived from exogenous substances, including cations such as lithium and anions such as salicylates, and formate generated from methanol, for example. All of these may potentially change the plasma pH when modifications in their concentration alter the normal relative proportion of plasma anions and cations. According to the electroneutrality principle and the constancy of the ionic product for water, the plasma concentration and activity of hydrogen ions depend on the plasma level of other ions, and variations in the plasma ionic composition predictably lead to a change in plasma pH.[26,29,33,40]

CO_2 and Bicarbonate-Physiologic Relationship and Effect on Acid-Base Balance

Plasma bicarbonate is a circulating anion that contributes substantially to the plasma negative charge in quantitative terms and therefore plays a role in defining plasma pH. Unlike other plasma ions, bicarbonate concentration is determined by the lung ventilatory activity besides the kidney handling of bicarbonate. Several isoenzymes of carbonic anhydrase are ubiquitously expressed in the human body and catalyze the reversible conversion of carbon dioxide into bicarbonate.[46] Carbon dioxide formed during cell metabolism continuously diffuses across the plasma membrane into the tissue capillary network, being transported by blood in a number of ways. Approximately 5% of the carbon dioxide remains as a gas in the aqueous phase of blood, measured as the partial pressure of carbon dioxide (PCO_2). An even smaller proportion of carbon dioxide binds to plasma proteins. Most of the carbon dioxide (90%-95%) arriving in capillary blood diffuses into the red blood cells, where it is hydrated to bicarbonate (HCO_3^-) by the cytosolic enzyme carbonic anhydrase II, generating hydrogen ions that bind to oxyhemoglobin.[33] As a result, oxygen is released from oxyhemoglobin and leaves the erythrocyte, reaching the tissues (see also Chapter 89). Bicarbonate formed inside the red blood cells by carbonic anhydrase II moves into the plasma in exchange for chloride through the plasma membrane transporter anion exchanger–1 (AE1). Erythrocytes with protonated deoxyhemoglobin formed in the tissue capillaries travel to the lungs, where the uptake of oxygen transforms deoxyhemoglobin into oxyhemoglobin, releasing hydrogen ions that are combined with bicarbonate diffusing back from plasma by carbonic anhydrase II, generating water and carbon dioxide, which is exhaled as a gas.[47]

Henderson clearly noticed the quantitative importance of the bicarbonate/carbonic acid buffering system when he developed his famous equation, a simple formula linking hydrogen ion concentration and the composition of an acid-base pair.[48] Henderson's equation was modified by Hasselbalch shortly after (Eqs. 9 and 10). The Henderson-Hasselbalch equation expresses the relationship of the bicarbonate/carbonic acid buffering system to pH:[21,33,36,48,49]

$$\mathrm{pH} = \mathrm{p}K_a + \log([\mathrm{HCO_3^-}]/[\mathrm{H_2CO_3}]) \qquad \textbf{(Eq. 12)}$$

The pH is equal to the $^-\log_{10}$ of the dissociation constant (pK_a) for H_2CO_3, plus the log of the ratio of HCO_3^- (proton acceptor) to H_2CO_3 (proton donor). The modified Henderson-Hasselbalch equation takes into consideration that most H_2CO_3 exists as dissolved CO_2 and is rewritten as follows[33,35,49]:

$$\mathrm{pH} = \mathrm{p}K_a + \log([\mathrm{HCO_3^-}]/0.03 \times \mathrm{PCO_2}) \qquad \textbf{(Eq. 13)}$$

where 0.03 is the solubility coefficient for carbon dioxide in blood at 37°C, and PCO_2 the partial pressure of CO_2 in blood.

The Henderson-Hasselbalch equation expresses how pH is affected by the change in the ratio of the concentration of undissociated acid HA (in this case carbonic acid or PCO_2) to the concentration of the conjugated base or anion A^- (in this case HCO_3^-).

At the physiologic values of pH, the ratio between HCO_3^- and the acidic component (CO_2—ie, carbonic acid) is 20 : 1. Knowing that HCO_3^-/H_2CO_3 (CO_2) is the only buffer system with a volatile component that can be regulated through the respiration, it is possible to have a clear appreciation of the pH alterations related to changes in PCO_2. When pH is altered as the result of changes in the volatile component (increases or decreases of PCO_2), the change is referred to as *respiratory,* because the primary alteration in the volatile component is always associated with either hypoventilation or hyperventilation.[34,35] When pH is modified by any other cause (ie, changes in nonvolatile acids [eg, lactic acid, ketoacids] or by changes in serum cations or anions [eg, hyper/hypochloremia]), the alteration is referred to as *metabolic* in origin.[21,29,34,35,49] Therefore this equation allows disorders to be classified according to the primary type of acid being increased or decreased. For example, if a patient's pH is low (acidemia), then the patient may have either an increased PCO_2 or a PCO_2 within normal or decreased values. If the PCO_2 is increased or at least higher than expected (alveolar hypoventilation), the condition is classified as *respiratory acidosis;* if this is not the case, the condition cannot be a respiratory acidosis. Therefore either some nonvolatile acid or a mineral-derived anion *must be* the cause of the acidemia, which is then referred to as *metabolic acidosis*. If these examples are reversed, then alkalemia conditions can also be classified as resulting from either respiratory or metabolic alkalosis.[34,35,44]

Thus the main usefulness of the Henderson-Hasselbalch equation is that it allows quantification of the severity of the respiratory component of the acid-base balance. For example, in a respiratory acidosis, the increase in the PCO_2 quantifies the derangement even when there are mixed disorders. The relationship between PCO_2 and HCO_3^- may provide a useful clinical guide for uncovering the metabolic origin of a given derangement in many rather simple acidosis cases, mainly the ones associated to the presence of organic acids; however, this is complicated by the fact that PCO_2, H_2CO_3, and HCO_3^- are all interlinked (Eqs. 11 to 13), so when bicarbonate increases, PCO_2 increases, and vice versa.[21,26,29,33,36,49] When taken as a mathematical expression of the relationship among its three variables, the equation is a valid statement of the dissociation equilibrium for carbonic acid. But the equation does not indicate, as is sometimes suggested, that pH is physically as well as mathematically determined by the values of $[HCO_3^-]$ and PCO_2. For this to be true, $[HCO_3^-]$ and PCO_2 would have to be able to vary independently of each other. In reality, both pH and $[HCO_3^-]$ are determined by PCO_2 in conjunction with other variables that are not included in the Henderson-Hasselbalch equation. Thus the Henderson-Hasselbalch equation does not provide information about acids other than CO_2/H_2CO_3, which means that only the HCO_3^-/CO_2 buffering system is being assessed, and the influence of other buffering systems and mineral anions and cations is overlooked.[21,26,41,48,49] In addition, the Henderson-Hasselbalch equation, as Henderson himself knew, was derived assuming that the concentrations of both the acid and the base were not modified by dissociation or hydrolysis, which is not necessarily true in physiologic conditions.[26,48,49] In systems with significant concentrations of nonvolatile weak acids, a change in PCO_2 causes a change in $[HCO_3^-]$—that is, it varies not only with metabolic but also with respiratory acid-base state. Hence the metabolic component

can only be approximated through the change in HCO_3^-.

The understanding that a rise in plasma CO_2 causes increased plasma HCO_3^- set the pace for the development of various refinements to quantify the metabolic component of acid-base disturbances, from the direct determination of pH and partial pressure of CO_2 (PCO_2), to the development of several tools for quantifying the metabolic component.[8,36,50,51] Because plasma bicarbonate is the principal means of transportation of carbon dioxide in blood, plasma bicarbonate level increases as carbon dioxide rises, whereas plasma bicarbonate concentration falls as carbon dioxide declines. Hence both carbon dioxide and plasma bicarbonate reflect mainly ventilatory status. Hypoventilation results in hypercapnia and a rise in plasma bicarbonate concentration, whereas hyperventilation leads to hypocapnia and a subsequent reduction in the plasma bicarbonate level. A quantitative relationship between carbon dioxide and plasma bicarbonate has been demonstrated in a number of situations, further highlighting this physiologic relationship.[33,36,50-57] Close attention must be paid to PCO_2, to pH, and to the clinical data and expected physiology and pathophysiology before an increased or decreased bicarbonate can be labeled as having a *metabolic* origin.[36,53-57])

Bicarbonate levels in blood are the result of the respiratory control of CO_2 elimination (quantitatively the largest influence), but they are also influenced by renal function, the presence of abnormal anions and acids in blood, liver function, and the potential abnormal loss of bicarbonate-rich fluids, as in diarrhea or renal tubular acidosis.[43,51,52,54-60] Therefore to rely only on the bicarbonate levels for the estimation of the metabolic component of an acid-base unbalance is an oversimplification that could be misleading in certain complex cases. For a single solution containing several weak acids (such as human plasma), all the weak acids are equilibrated with a single pool of hydrogen ions. In other words, all buffering systems, which participate in keeping the acid-base balance, are in equilibrium with each other. This is called the *isohydric principle*.[21] It may be illustrated with two buffer systems: bicarbonate/carbonic acid and phosphate/phosphoric acid:

$$H_2CO_3 \leftrightarrow HCO_3^- + H^+ + HPO_4^{2-} \leftrightarrow H_2PO_4^- \qquad \textbf{(Eq. 14)}$$

In this equilibrium H^+will eventually form both carbonic acid and phosphoric acid from the single H^+ plasmatic pool. Expressing the same concept in the Henderson-Hasselbalch way:

$$\begin{aligned} pK_{a1} + \log([HCO_3^-]/[H_2CO_3]) &= pH \\ &= pK_{a2} + \log([HPO_4^{2-}/[H_2PO_4^-]) \end{aligned} \qquad \textbf{(Eq. 15)}$$

Thus according to the isohydric principle, the ratio of *any pair* of conjugate base or anion and its undissociated acid will be able to describe the $[H^+]$ or pH.[21,26] This means that although the ratio of PCO_2 to bicarbonate can describe the pH and the respiratory component of the acid-base status, this buffering system is not necessarily the primary or underlying mechanism for explaining by itself all the

changes in pH, nor may the changes in bicarbonate explain by themselves all the possible derangements of the metabolic component.[21,29] This is particularly true in the so-called mixed or complex cases.

Many physiologists focused on the plasma bicarbonate concentration and the Henderson-Hasselbalch equation, neglecting almost entirely all other influences on acid-base status.[21,41,49] This was the beginning of the still dominant concept that plasma bicarbonate is not only the best indicator of acid-base status but also the main determinant of it. Immersed in the bicarbonate-centered approach, investigators yielded basically two solutions for analyzing the metabolic side of the equation: the base excess method and the six bicarbonate rules of thumb. The role of the mineral anions was also taken into account, albeit not in an integrated way, by the use of anion gap (AG). Stewart's physicochemical approach appeared later.[21,35,36,61-63]

Tools for Interpreting Acid-Base Disorders

The understanding that a rise in plasma CO_2 causes increased plasma HCO_3^- set the pace for the development of various refinements to quantify the metabolic component of acid-base disturbances. In an attempt to identify acid-base changes independent of carbon dioxide, Singer and Hastings advanced the concept of a *buffer base (BB),* which is the sum of weak acids (buffer anions) in plasma—that is HCO_3^- and all nonvolatile weak acid buffers, albumin included; they also defined fixed acids as nonbuffer anions, chloride being one.[8,21,26,64,65] Other research groups later proposed several PCO_2-independent indicators of nonrespiratory acid-base disturbances. One is the *standard bicarbonate,* which is measured plasma HCO_3^- at a $PaCO_2$ of 40 mm Hg (5.33 kPa).[66] *Base excess or deficit (BE),* developed by Siggard-Andersen in 1963, is another indicator, which is a measure of the deviation of BB from its normal value.[67] Two trends developed, one relying on plasma [HCO_3^-] and the other on BE for detection of metabolic acidosis or alkalosis. Both base excess and bicarbonate rules of thumb use a bicarbonate-centered approach. Indeed, both approaches can detect metabolic disturbances, mostly the simple ones, but if PCO_2 varies, the picture may be blurred.[8,21,26] A singular change in either [HCO_3^-] or BE does not differentiate among the various possible sources of nonrespiratory acid-base disturbances. Such a determination is often important in clinical medicine.

Base Excess and Standard Base Excess

The change in pH of a given buffered solution is dependent on both the amount of strong acid (or strong base) that is added and the buffering capacity of the system. As acid is added, for every H^+ that is buffered, one molecule of conjugate base of the buffer is consumed. Therefore quantifying the changes in the concentration of the conjugate base of the buffer is more useful than the degree of change in the pH in estimating the number of nonvolatile acids present. Siggaard-Andersen, from Copenhagen, developed the *base excess method* in the late 1950s and early 1960s.[26,36,66-68]

Base excess (BE) is defined as the amount of strong acid (or strong base) in mol/L that must be added in vitro to a whole blood sample to return the pH of the sample

to 7.4 while the PCO_2 is kept constant at 40 mm Hg.[8,21,26,66-69] Therefore if the blood sample is normal (ie, pH is 7.4 and PCO_2 is about 40 mm Hg), the BE will be 0 mmol/L. Positive values mean literally an excess of metabolic bases; negative values mean an excess of metabolic acids.[35,68-70] To apply the BE to the clinical setting, a nomogram was developed, which was later mathematically transcribed to allow BE calculation by blood gas analyzers.[68,70-73] BE, even though calculated, comes closest to being the parameter that is least influenced by changes in $PaCO_2$. However, several limitations appeared.[70,73-75] For clinical accuracy, other assumptions had to be incorporated (correction factors, adjusted formulas, nomogram modifications),[21,68,70,72,76] and remarkably an empiric estimate of hemoglobin concentration throughout the entire extracellular fluid space (whole blood plus interstitial fluid) had to be established. The original BE was calculated only for plasma buffers. As Hb is the main buffer in blood, changes in Hb can significantly affect BE. To take into account the net effect of all the buffers of the body, the three compartments relevant to acid-base balance—plasma, erythrocytes, and interstitial fluid—had to be considered, including the influence of hemoglobin.[26,33,76] The chosen hemoglobin concentration was 50 g/L (5 g/dL) as an estimation of the concentration of hemoglobin as it is diluted throughout the body. This estimation is, of course, somewhat arbitrary. For example, in a patient with a hemoglobin concentration of 5 mg/dL from the outset, the impact of the interstitium is not actually taken into account.[70,76] BE calculated this way is called *standard base excess (SBE),* a parameter reported nowadays by modern gas analyzers and used in the classical approach to acid-base balance (Table 76.1). Although SBE has good correlation with bicarbonate levels and quantifies the change in metabolic acid-base status in vivo, its accuracy depends on the 5 g/dL of hemoglobin assumption. It does not provide information about the origin or mechanisms of the metabolic acid-base derangement because SBE is not a substance that can be regulated, absorbed, or excreted by the body.[29] Perhaps the main drawback is that SBE value represents the net effect of all metabolic acid-base abnormalities. Therefore the effect of coexisting metabolic acidosis and alkaloses may cancel each other, and the “normal figure” of the SBE will mistakenly suggest that no acid-base derangement exists. Actually, 15% to 18% of critically ill adults with acid-base disorders have normal SBE.[61,77] In practice, SBE is calculated by well-established formulas or derived from nomograms.[68,69] Nomograms are widely incorporated in blood-gas analyzer software and SBE calculated from variables like pH, HCO_3^-, and Hb. Simple mathematical rules can be applied for using SBE in common acid-base disturbances.[8,9,69] Thus SBE does not change in acute respiratory acidosis or alkalosis. In metabolic acidosis, SBE decreases and becomes negative (−BE or base deficit), whereas it becomes positive in metabolic alkalosis (simply called BE or +BE). However, calculating SBE is not without its inconveniences. SBE can still vary with changes in $PaCO_2$, albeit only slightly, and may be unreliable in the presence of low albumin or phosphate levels. Other drawbacks include inaccuracy due to in vitro measurement and that it does not take into account the respiratory status or the volume of distribution of bicarbonate.[9]

TABLE 76.1

Classical Acid-Base Parameters

pH	$\log_{10} H^+$. Measured directly by electrode. Normal = 7.35-7.45.
PCO_2	Partial pressure of gaseous CO_2. Measured directly by electrode. Usually expressed in mm Hg. Normal value: 35-45 mm Hg (sea level, arterial blood).
HCO_3^-	Bicarbonate concentration. A calculated parameter, derived from pH and PCO_2 values using a nomogram or the Henderson-Hasselbalch equation, or equal to the difference between serum total CO_2 (CO_{2TOT}) and the dissolved CO_2. ($PCO_2 \times 0.03$). Normal value: 22-28 mEq/L.
Base excess (BE or BE/D)	Also known as base excess/deficit. Defined as the amount of strong base (negative base excess, or "base deficit") or strong acid (positive base excess) in mmol/L that would be needed to restore a pH of 7.4 to a liter of whole blood equilibrated at PCO_2 = 40 mm Hg. It is calculated by a nomogram or equation that was derived from an experimental series of in vitro titrations of strong acid and base in whole blood samples at various PCO_2 levels. It excludes the effect of acute changes in PCO_2, so it loses accuracy if PCO_2 is abnormal. It should not be used in critically ill patients.
Standard base excess (SBE)	An improvement of base excess to allow equilibration across the entire extracellular fluid space (whole blood interstitial fluid) and thus preserve accuracy at variable PCO_2 values. The new equation assumes an average concentration of hemoglobin through that space of 5 g/dL. Despite being a somewhat arbitrary figure, it indeed works in vivo.
CO_{2TOT} or CO_2	Total CO_2 or CO_2 concentration. A serum chemistry measured value. Its components include HCO_3^-, dissolved gaseous CO_2, carbonic acid (H_2CO_3), carbamino CO_2, and carbonate (CO_3^{2-}). About 95% exists as HCO_3^-, and 4% to 5% as dissolved gaseous CO_2. Remaining species are negligible. Because the difference between CO_{2TOT} and HCO_3^- is about 1 mEq/L at physiologic pH, for clinical purposes they are taken almost as equivalents.
Anion gap (AG)	A calculated value that, taking advantage of the electroneutrality principle that rules plasmatic ions (total number of cations should be the same as the total number of anions), indicates the presence of unmeasured anions (mostly organic acids). $AG = (Na^+ + K^+) - (Cl^- + HCO_3^-)$. Normal values are 16 mEq/L (if K^+ is included) or 12 mEq/L (without K^+, with variations of ± 2 to 4 mEq/L. These values may be influenced by the way the values of some of the parameters are measured, so it is always better to consult each institution's own expected normal AG.
Corrected anion gap (AG_{CORR})	An improvement in the calculation of AG that acknowledges that an increase in AG from organic acids may be masked by a decrease in AG from low protein (albumin) levels. AG is corrected for the patient's own albumin concentration as follows: $AG_{CORRECTED} = AG_{OBSERVED} \times 2.5$[normal albumin (g/dL)] − [observed albumin (g/dL)], considering normal albumin from 3.2 to 4.5 g/dL. To avoid [lactate$^-$] influence on AG_{CORR} that could mask the detection of other unmeasured anions, it has been suggested that AG should be corrected not only for albumin but also for lactate. This is simply made by subtracting the serum lactate concentration (in mmol/L) from the already albumin-corrected AG: $AG_{CORRLACT}$ = Albumin-corrected AG − [lactate$^-$ (mmol/L)].
Urinary anion gap (uGap)	The same principle of the anion gap applied to urinary ions—that is, uGap estimates unmeasured urinary ions. It has also been designated by some as the urine strong ion difference (uSID), a functionally correct name, as all the involved ions are strong ions: $uGap = uSID = [uNa^+ + uK^+] - [uCl^-]$. The most important unmeasured urinary strong anion (Ur^-) is SO_4^{2-} (derived from the metabolism of sulfur amino acids), whereas the most important unmeasured cation (Ur^+) is ammonium (NH_4^+). In physiologically normal conditions, uSID must equal the plasmatic SID_{APP}, or 38-42 mEq/L.

Bicarbonate Rules of Thumb

Strong criticism of the SBE in the great transatlantic debate[21,41,49,72-75] yielded the six bicarbonate rules of thumb[72,73] (Table 76.2). Because the body always seeks to tightly control [H^+], when an acid-base derangement tends to appear, several physiologic responses become active over time, and then the relationship between PCO_2 and HCO^-_3 expressed in the Henderson-Hasselbalch equation is modified so pH changes can be minimized. On the observation of many patients with clearly defined alterations of the acid-base balance, Schwartz and Relman[73] concluded that several global patterns could be detected. With this Boston school *six rules of thumb* approach, it is possible to predict to what extent changes in pH and PCO_2 modify the concentration of bicarbonate in an acute alteration or a chronic respiratory disorder. Similarly, even primary metabolic disorders can be predicted, based on changes in the PCO_2 in the context of a normal respiratory compensation (assuming normal respiratory function).[70] These rules are useful for uncovering mixed disorders, to

differentiate acute from chronic respiratory unbalances, and to describe the physiologic compensation to acid-base changes to optimize acid-base homeostasis (Tables 76.2 and 76.3). $[H^+]$ is related to CO_2 in respiratory and to CO_2/HCO_3^- in metabolic acid-base disturbances. This approach is easy to use in stable patients exhibiting simple acid-base disturbances, where the magnitude of increase in unmeasured anions parallels the drop in $[HCO_3^-]$. However, as $[HCO_3^-]$ varies with changes in $PaCO_2$, the severity of the nonrespiratory (metabolic) component of acid-base disorders and the nature of acids other than carbonic are difficult to assess. The CO_2/HCO_3^- approach is mostly applied to determine resting $PaCO_2$ in patients with chronic respiratory failure.[8,9]

TABLE 76.2

Classical Acid-Base Approach: Observational Acid-Base Patterns

Primary Disorder	Expected Changes $[HCO_3^-]$ (mEq/L or mmol/L)	Expected Changes PCO_2 (mm Hg)*	Expected Changes SBE (mmol/L)
Metabolic acidosis[a]	Primary decrease <22	**Bicarbonate Approach** $PCO_2 = (1.5 \times HCO_3^-) + (8 \pm 2)$ or PCO_2 ↓ 1.2 − 1.5 mm Hg for each mEq/L $[HCO_3^-]$ ↓ **SBE Approach** $PCO_2 = 40 \pm SBE$, or PCO_2 ↓ 1 mm Hg for each mEq/L SBE ↓	Base deficit <−3
Metabolic alkalosis[b]	Primary increase >26	**Bicarbonate Approach** $PCO_2 = (0.7 \times HCO_3^-) + (21 \pm 2)$ or PCO_2 ↑ 0.7 mm Hg for each mEq/L HCO_3^-] ↑ **SBE Approach** $PCO_2 = 40 \pm (0.6 \times SBE)$, or $PaCO_2$ ↑ 0.6 mm Hg for each mEq/l $[HCO_3^-]$ ↑	Base excess >+3
Acute respiratory acidosis	$= [(PCO_2 - 40)/10] + 24$ or $[HCO_3^-]$ ↑ 0.1 mEq/L for each mm Hg PCO_2 ↑	Primary PCO_2 increase >45 $\Delta pH = 0.008 \times (PCO_2 - 40)$	0
Chronic respiratory acidosis	$= [(PCO_2 - 40)/3] + 24$ or $[HCO_3^-]$ ↑ 0.3 mEq/L for each mm Hg PCO_2 ↑	Primary PCO_2 increase >45 $\Delta pH = 0.003 \times (PCO_2 - 40)$	$0.4 \times (PCO_2 - 40)$ or SBE ↑ 0.4 mEq/L for each mm Hg PCO_2 ↑
Acute respiratory alkalosis	$= [(40 - PCO_2)/5] + 24$ or $[HCO_3^-]$ ↓ 0.2 mEq/L for each mm Hg PCO_2 ↓	Primary PCO_2 decrease <35 $\Delta pH = 0.008 \times (40 - PCO_2)$	0
Chronic respiratory alkalosis	$= [(40 - PCO_2)/10] + 24$ $[HCO_3^-]$ ↓ 0.4 mEq/L for each mm Hg ↓ PCO_2	Primary PCO_2 decrease <35 $\Delta pH = 0.017 \times (40 - PCO_2)$	$0.4 \times (PCO_2 - 40)$ or ↓ 0.4 mEq/L for each mm Hg ↓

*Always adjust PCO_2 values to the height above sea level. Empirical rules for expected values and compensation are minimally affected.

[a]In metabolic acidosis, hyperventilation PCO_2 decreases in a highly predictable fashion, if respiratory and CNS function are normal.

[b]In metabolic alkalosis, compensatory respiratory hypoventilation is highly variable even if respiratory and CNS function are normal.

Acute = minutes to hours; chronic = several days or longer.

See Table 76.3.

SBE, standard base excess.

TABLE 76.3

Classical Acid-Base Approach: Additional Clues

1. A metabolic acid-base derangement exists if any of the following occurs:
a. pH is abnormal.
b. pH and PCO_2 have changed in the same direction (both increased or both decreased).
c. Respiratory compensation is intact if $PaCO_2$ resembles last two digits of pH (eg, pH 7.23 and $PaCO_2$ ≤23 mm Hg).
2. A respiratory acid-base derangement is overlapped if any of the following occurs:
a. pH is abnormal but PCO_2 is reported within normal limits.
b. PCO_2 reported is higher than expected PCO_2 (respiratory acidosis overlapped).
c. PCO_2 reported is lower than expected PCO_2 (respiratory alkalosis overlapped).
3. A respiratory acid-base derangement exists if any of the following occurs:
a. $PaCO_2$ is abnormal.
b. PCO_2 and pH have changed in opposite directions (ie, raised PCO_2 and decreased pH or vice versa).
4. If the change of pH is … (see formulas in Table 76.2)
a. 0.008 × change in PCO_2, there is no compensation; then the derangement is acute.
b. >0.003 but <0.008 × change in PCO_2, there is a partial compensation.
c. 0.003 × change in PCO_2, there is full compensation; then the derangement is chronic.
d. >0.008 × change in PCO_2, there is an overlapping metabolic derangement.
5. There is a mixed derangement (acidosis and alkalosis) if any of the following occurs:
a. $PaCO_2$ is abnormal and pH has not changed as expected or is within normal values.
b. pH is abnormal and $PaCO_2$ has not changed as expected or is within normal values.

Modified from Marino PL. Acid-base interpretations. In: The Little ICU Book of Facts and Figures. Philadelphia: Lippincott Williams & Wilkins; 2009:349-362.

Anion Gap and Corrected Anion Gap

The anion gap (AG) was first suggested by Emmet and Narins as a complementary diagnostic tool for either SBE or bicarbonate rules of thumb approaches of metabolic disturbances, particularly the metabolic acidoses.[77] It is based on the principle of electroneutrality, which states that in an aqueous solution like plasma and intracellular fluid there is no net electrical charge.[33] Accordingly, serum positive-charged cations must equal serum negative-charged anions[26,35](see Table 76.1):

$$[Na^+]+[K^+]+[Ca^{2+}]+[Mg^{2+}]+[H^+] = [Cl^-]+[HCO_3^-]+[proteins^-]+[PO_4^{2-}] + [SO_4^{2-}]+[OH^-]+[CO_3^{2-}]+[lactate^-]+[XA^-]) \quad \textbf{(Eq. 16)}$$

where $[XA^-]$ equals the unmeasured acid anions (UMAs). The plasma concentrations of SO_4^{2-}, OH^-, CO_3^{2-}, and H^+ ($H_3O_2^+$) are quite small and can be neglected, whereas Ca^{2+} and Mg^{2+} are omitted by convention.

Concentrations of Na^+, K^+, Cl^-, and HCO_3^- (in the form of total CO_2) are reported in a standard chemistry panel, and hence they are used for AG calculation. Thus AG is commonly defined as follows:[8,35]

$$AG = ([Na^+]+[K^+]) - ([Cl^-]+[HCO_3^-]) \qquad \textbf{(Eq. 17A)}$$

If $[K^+]$ is omitted and its effect neglected,[78]

$$AG = [Na^+] - ([Cl^-]+[HCO_3^-]) \qquad \textbf{(Eq. 17B)}$$

The sum of the difference in charge carried by these four commonly measured extracellular cations and anions reveals a gap of about 12 to 16 mmol/L or mEq/L. The gap value accounts for unmeasured anions (lactate, ketones, sulfate, etc). Typically, normal values are 16 mEq/L or mmol/L if $[K^+]$ is included or 12 mEq/L without it, with variations of ±2 to 4 mEq/L. However, this classical reference value is now lower and narrower because of the use of the ion-selective electrode, which provides higher chloride values than previous techniques. Several studies have reported "normal" AG values (K^+ not included) as 6.6 ± 2 mEq/L (range, 2.6 to 10.6 mEq/L).[79-81] Because AG value may be highly influenced by the way the concentrations of the parameters are measured, it is always better to consult each institution's own expected normal AG.[8,79]

It must be realized that calculated AG is affected by any change in the concentrations of either the UMAs or the cations not included in Eqs. 17A and 17B.[82] If AG increases, this is due to the accumulation of anions, like lactate or ketones, that are not measured, which cause a compensatory drop in chloride or bicarbonate levels, for the sake of electroneutrality. This condition is termed *widened anion-gap acidosis* or just *gap acidosis.* The AG approach is actually the principal method for detecting unmeasured anions as the cause of metabolic acidosis (lactic acidosis, acidosis caused by specific substances, ketoacids, etc.).[82] However, some considerations must be kept in mind.[83]

Plasma proteins and phosphate levels can be significantly decreased in the critical care setting. Reduced protein and phosphate levels result in a decreased UMA and hence in a decreased AG. Therefore an increase in AG from organic acids may be masked by a decrease in AG from low protein and phosphate levels, and therefore it is wise to make the proper corrections.[78,83] This is particularly true in the pediatric critical care setting, where hypoalbuminemia is nearly ubiquitous.[84,85] Phosphate and globulin influence is rather small because their pK_a is much greater than plasma pH (they do not easily dissociate) and hence they do not have a significant charge contribution. Figge and colleagues showed that in most patients, the AG could be corrected (AG_{CORR}) as follows[78]:

$$\begin{aligned} AG_{CORR} = AG_{OBSERVED} + 2.5\,&[\text{normal albumin g/dL}] \\ &- [\text{observed albumin g/dL}] \end{aligned} \qquad \textbf{(Eq. 18A)}$$

or

$$\begin{aligned} AG_{CORR} = AG_{OBSERVED} + 0.25\,&[\text{normal albumin g/L}] \\ &- [\text{observed albumin g/L}] \end{aligned} \qquad \textbf{(Eq. 18B)}$$

considering normal albumin 3.2 to 4.5 g/dL.

The albumin-corrected AG (AG_{CORR}) can unmask an organic acidosis previously undetected in the setting of hypoalbuminemia, and it adds sensitivity for detecting unmeasured anions, including lactate, although the specificity for hyperlactatemia is poor.[8,86-88] Thus lactate must be directly determined.

Despite the fact that it is not useful for quantifying the metabolic derangement, AG is a powerful tool for the clinician in the categorization of metabolic acidoses, as not all metabolic acidoses result in an elevated AG.[83] As a hypothetical example, consider that acid in the form of HCl is added to the circulation. Upon dissociation, Cl^- remains as the conjugate base while the plasmatic bicarbonate buffer is “consumed” by the hydrogen ion. The result is that an increase in $[Cl^-]$ is balanced by a decrease in $[HCO_3^-]$ (ie, there is metabolic acidosis without a change in the AG). Employing the AG_{CORR} it is possible to differentiate hyperchloremic acidosis (normal AG) from gap acidoses (increased AG).[78,83] The last category includes all conditions of metabolic simple acidosis caused by increased concentrations of nonvolatile anions other than chloride, usually unmeasured (or unmeasurable), such as lactate, ketoacids, phosphate, sulfates (and other anions in renal failure setting), salicylate, some β-lactam antibiotics, organic acids from congenital errors of metabolism, and acetate from parenteral nutrition[83,86] (Table 76.4). Non-AG, hyperchloremic acidoses include an excessive infusion of chloride salts (saline or parenteral nutrition) and increased renal or gastrointestinal bicarbonate losses. Alternatively, metabolic alkalosis may stem from hypochloremia resulting from chloride loss or bicarbonate gain and from hypoalbuminemia.[86] AG performance is not so good in mixed acid-base physiology despite several attempts to improve it. This represents an important limitation for its use in critical care patients, in whom single metabolic acid-base disorders are more the exception than the rule. Bicarbonate itself represents another potential unstable variable in the AG equation, as it can potentially be influenced by certain therapeutic interventions, such as furosemide infusion, deliberate hyperventilation in head trauma, or permissive hypercapnia in acute respiratory distress syndrome.[8]

TABLE 76.4

Causes of Metabolic Acidosis in Critically Ill Patients

I. Accumulation of Unmeasured Anions: The Anion Gap Acidoses
A. Endogenous Source of Acids
1. Type A hyperlactatemia (decreased tissue O_2 delivery)
2. Type B hyperlactatemia (not associated with tissue hypoxia)
a. Adrenalin infusion
b. Reactive hyperglycemia
c. Liver failure
d. Drug-induced mitochondrial inhibition (eg, linezolid)
e. Miscellaneous
3. Ketoacidosis (diabetic, alcoholic, starvation, inborn errors of metabolism)
4. Renal failure: accumulation of phosphates, sulfates, and organic ions
5. Unidentified anions in sepsis other than lactate
6. Organic acids from inborn errors of metabolism
7. Late metabolic acidosis of prematurity
B. Exogenous Source of Acids
1. Ingested toxins and drugs that directly provoke acidosis
a. Methanol, formic acid, keto acids, lactate
b. Ethylene glycol, glycolic acid, oxalic acid, paraldehyde
c. Ethanol
d. Salicylate, salicylic acid, acetic acid

e. Nonlegal drugs 2. Total parenteral nutrition[a]
II. Hyperchloremic Acidoses: The Nonanion Gap Acidoses
A. Exogenous Chloride Load
1. Normal saline or hypertonic saline resuscitation 2. HCl, NH_4Cl, arginine-HCl administration 3. Total parenteral nutrition[a]
B. Loss of Cations From the Lower Gastrointestinal Tract (Postpyloric Gastrointestinal Fluid Losses)[b]
1. Infectious secretory diarrhea and dehydration 2. Short bowel syndrome 3. Drainage from ostomies, tubes, fistulas (small bowel, pancreatic, or biliary drainage) 4. Sulfamylon, cholestyramine
C. Renal Causes[c]
1. Chronic renal insufficiency (impaired ammonium [NH_4^+] generation) 2. Renal tubular acidoses 3. Hypoaldosteronism 4. Recovery phase of diabetic ketoacidosis 5. Urinary tract obstruction 6. Drug-mediated loss of cations and tubulopathies a. Acetazolamide b. Amphotericin B c. K^+-sparing diuretics
D. Urinary Reconstruction Using Bowel Segments

[a]Total parenteral nutrition may cause both anion gap and nonanion gap acidosis. In the first case, an excessive amount of exogenous acid is the cause, mainly if liver or renal functions are impaired; in the latter, an unbalanced, excessive chloride content in the formulation provokes the derangement, which is easily produced in the setting of renal failure.

[b]This class corresponds to the gastrointestinal loss of the bicarbonate type of acidosis, according to the classical approach to A-B.

[c]This class corresponds to the renal loss of the bicarbonate type of acidosis, according to the classical approach.

Physicochemical Approach: Interacting Chemical Mechanisms Regulate pH

In the late 1970s and early 1980s, Peter Stewart developed a mathematical model of acid-base balance through the application of several basic principles of physical chemistry, particularly electroneutrality, conservation of mass, and dissociation equilibrium of partially dissociated substances (law of mass action).[8,21,26,29,61,89] Electroneutrality states that in aqueous solutions the sum of all positively charged ions must equal the sum of all negatively charged ions. In pure water for the system, $H_2CO_3 \leftrightarrow HCO_3^- + H^+$, the concentration of H^+ ions should be equal to the concentration of HCO_3^- ions. But biological fluids are complex and dynamic systems, in which multiple mechanisms are involved in influencing the particular concentration of any single chemical species. Hydrogen ion is an example of one of these species whose concentration depends on several interacting chemical mechanisms that must equilibrate so the [H+] (or pH) in the solution at that point in time can be determined. To calculate the equilibrium concentration of any species, one must take into account all the mechanisms involved. In plasma, for example, the other charged ions present also have an effect on the relative proportions of H^+ and HCO_3^-. Plasma is an aqueous solution that contains strong ions that are completely dissociated at physiologic pH, weak acids that are partially dissociated at physiologic pH, and carbon dioxide that is in equilibrium with an external partial pressure of carbon dioxide. These other charged molecules, which affect the dissociation of water to generate H^+, can be classed into three independent

controlling variables of H^+ concentration[8,21,26,27]:

1. *Partial pressure of carbon dioxide (PCO_2).* In arterial blood plasma, PCO_2 is primarily regulated by PCO_2 in alveolar gas, with the consequence that all fluid compartments of the body can be considered as open systems with regard to CO_2.

2. *The strong ion difference (SID).* Blood plasma contains numerous ions, which may be classified not only in regard to their electrical charge (cations are positive, anions are negative) but also according to their tendency to dissociate. Some ions are fully dissociated in aqueous solutions and are called *strong ions,* such as Na^+, K^+, Ca^{2+}, Mg^{2+}, and Cl^-. Others, such as albumin, phosphate, and HCO_3^-, can exist both as charged (ie, dissociated) and uncharged forms and are called *weak ions.* Certain organic acids, such as lactate and others, are nearly completely dissociated under physiologic conditions, and so they are considered strong ions. In blood plasma, strong cations outnumber strong anions. The difference between the sum of all of the strong cations and that of all of the strong anions is called *strong ion difference (SID),* which represents the net electric charge on the strong ions (ie, electrolytes, lactate, and certain highly dissociated acids). Sodium and chloride are the two most important plasmatic strong ions. In plasma, strong ions are primarily regulated by the kidneys so that body fluids are an open system for water and electrolytes.[8,21,26]

3. *The total concentration of nonvolatile weak acids (A_{TOT}).* That is, for each of them this variable represents the sum of its dissociated and undissociated forms ($A_{TOT} = A^- + HA$).[26,27,32] Weak acids are not fully dissociated at physiologic pH; the most important of them is albumin, with a minor effect from phosphate. The system H_2CO_3/HCO_3^- is also a weak acid, but it has already been considered as a part of the PCO_2.

According to Stewart's calculations, *independent variables* mean that PCO_2, SID, and A_{TOT} are *causally* related to the hydrogen ion, rather than being merely correlated.[26,27] The traditional acid-base analysis makes the implicit assumption that $[H^+]$ is an independent variable, but this is not a physicochemically solid statement.[12,13,26,35,36,38] Normal acid-base status occurs when the independent variables have normal values. Abnormality of one or more of the independent variables underlies all acid-base disturbances. Adjustment of the independent variables is the essence of all therapeutic interventions because none of the dependent variables (eg, pH, BE, or $[HCO_3^-]$) can be changed primarily or individually; the dependent variables change all of them simultaneously if, and only if, one or more of the independent variables change.[26,29,61] Because PCO_2 is regulated by respiration, its changes result in respiratory acid-base disorders. Metabolic acid-base disorders stem from changes in either SID or A_{TOT}, regulated by kidney and physical-chemical interactions in body fluids.

CO_2 and Bicarbonate in Stewart's Approach

In Stewart's approach, CO_2 is an independent determinant of pH. However, the role of bicarbonate is reduced from being causative to a mere indicator, as hydrogen ion and bicarbonate concentrations are totally dependent on the three independent

controlling variables noted earlier. Hence, according to Stewart, the major use for the bicarbonate rules of thumb and SBE is to determine the extent of the clinical acid-base disorder, rather than the mechanism.[8,21,26,29]

The rise of the PCO_2, according to the Henderson-Hasselbalch equation (Eq. 13), will increase both H^+ and HCO_3^- concentrations. Therefore the change in HCO_3^- concentration is mediated by chemical equilibrium (Eq. 11) and not by any systemic adaptive response.[29] The total CO_2 concentration (and hence the $[HCO_3^-]$) is determined by the PCO_2, which is in turn determined by the balance between alveolar ventilation and CO_2 production at the tissue level. Therefore HCO_3^- cannot be regulated independently of PCO_2. Plasma bicarbonate concentration will always increase if PCO_2 increases, but this is not an alkalosis. Therefore the increased bicarbonate concentration is not *buffering* the rise of $[H^+]$, and there will be no change in the SBE. As CO_2 easily diffuses through membranes, when PCO_2 increases there is always tissue acidosis. If PCO_2 remains high, the body will attempt to compensate by increasing renal bicarbonate production.[26,29] The same response, but in the opposite direction, occurs when PCO_2 drops.[89]

Strong Ion Difference: Apparent and Effective

SID is defined as the charge difference between the sum of all strong cations and the sum of all strong anions. When SID is calculated from direct measurement of serum-strong ions, it is termed *apparent* SID (SID_{APP}),[29,86,90] with the understanding that more unmeasured (or unmeasurable) ions might also be present (Table 76.5):

$$SID_{APP} = ([Na^+]+[K^+]+[Ca^{2+}]+[Mg^{2+}]) - ([Cl^-]) \qquad \textbf{(Eq. 19A)}$$

Unless elevated, lactate is ignored, as its contribution to total SID is negligible. In the critical care setting, the sicker the patient, the higher the chance that lactate or other strong anions are increased; thus lactate should be include in those cases:

$$SID_{APP} = ([Na^+]+[K^+]+[Ca^{2+}]+[Mg^{2+}]) - ([Cl^-]+[lactate^-]) \qquad \textbf{(Eq. 19B)}$$

TABLE 76.5

Tools for the Assessment of the Acid-Base Balance

	BICARBONATE-CENTERED APPROACHES		PHYSICOCHEMICAL APPROACH
Tool	**Bicarbonate "Rules of Thumb"**	**Base Excess/Deficit (BE)**	**PCO_2/SID-SIG/A_{TOT}**
Foundation	Henderson-Hasselbalch equation; "rules" and figures empirically derived Brønsted-Lowry acids	Henderson-Hasselbalch equation and chemical principles of acid-base titration Brønsted-Lowry acids	Principles of electrical neutrality and product ionic for water, law of mass action, behavior of cations and anions in mixed aqueous solutions Arrhenius (Van Slyke) and Brønsted-Lowry acids
Determinations	pH and PCO_2 only	Calculated from measured pH, PCO_2 (BE), and	pH, PCO_2 measured

	parameters actually measured	hemoglobin (SBE) Needs several assumptions	SID_{APP} SID_{EFF}, SIG, A_{TOT} calculated from measured cations and anions
			SID_{APP} = ([Na^+] + [K^+] + [Ca^{++}] + [Mg^{++}] + [$lactate^-$] + [other strong anions])
			SID_{EFF} ={HCO_3^-] + [Alb^-] + [Pi^-] [Alb^-] = [Alb^-] × [(0.123 × pH) − 0.631] [Pi] = [Pi, mmol/L] × [(0.309 × pH) − 0.469]
			SIG = SID_{APP} − SID_{EFF}
			A_{TOT} = 2.43 × [total protein, g/dl]
Application	Simple acid-base derangements	Simple acid-base derangements	Simple and complex acid-base derangements
	Bedside and point-of-care gas analyzers	Bedside and point-of-care gas analyzers	Lab info available bedside with most blood analyzers; full lab required for albumin and phosphate
Caveats	"Rules" of PCO_2 and HCO_3^- are valid only in not so extreme pH values	Does not give direct information about mixed or complex derangements	Original equations complex and no suitable for bedside; needs consultation online or specific app
	"Rules" must be adjusted for chronic situations	Not reliable in patients with extreme values of Hb or severely edematous	Abridged equations (presented here) still complex and cumbersome
	Mixed and complex derangements are empirically interpreted	"Normal" values reported between +/−2 up to +/−5	Needs total proteins, albumin, and every electrolyte available
			Need more lab determinations, higher chance for analytic error
			More expensive
Need complement?	Yes. Anion gap: ([Na^+] + [K^+] − [Cl^-] + HCO_3^-])	Yes. Anion gap: ([Na^+] + [K^+] − [Cl^-] + HCO_3^-])	No, but surrogates are convenient for bedside: —[Na^+] − [Cl^-] for SID_{APP} —$AG_{CORRLACT}$ for SIG
	PCO_2 and HCO_3^- do not change independently from one another (neither physiologically nor mathematically)	Both BE and SBE are artificial chemical indexes (body does not secrete or excrete them); in order to be calculated, blood sample must be kept at 37°C and PCO_2 is assumed to be in 40 mm Hg; for SBE it is assumed an average Hb of 5 g/dl throughout the body fluids	Applies only for plasma
Expected "normal" values	Well defined, need adjustment according to height above sea level	+/−3 dimensionless	—SID_{APP} = 38-42; 33 ± 5.6 in most "stable" critical care patients —SID_{EFF} = Sum of HCO_3^- plus expected electric charges of nonbicarbonate buffers (albumin + Pi) —SIG = <8 mEq/L or mmol/L

All variables expressed in mEq/L unless expressed otherwise.

Alb^-, in g/L; *A_{TOT}*, total concentration of weak acids in plasma; *BE*, base excess; *Hb*, hemoglobin (g/dl); *Pi^-*, inorganic phosphate, in mmol/L; *SBE*, standard base excess; *SID_{APP}*, strong ion difference (apparent); *SID_{EFF}*, strong ion difference (effective); *SIG*, strong ion gap.

Ca^{++} and Mg^{++} in ionized concentrations.

Surrogates can be used: [Na^+] − [Cl^-] for SIDAPP; Anion gap corrected for albumin and lactate for SIG. (See Fig. 76.1.)

From actual measurements in healthy volunteers, the "normal" range of SID_{APP}

has been estimated to be from 38 to 42 mEq/L.[21,29,61,91] In critical illnesses, SID_{APP} may be substantially reduced, even when there is no evidence (by the traditional approach) of a metabolic acid-base derangement.[79,92,93] In "stable" critical care patients, SID_{APP} values have been reported to be between 33 ± 5.6 mEq/L[92] and 41.5 ± 5.1 mEq/L.[79] Thus in spite of the lack of consensus about what value of SID_{APP} one should expect in an ICU population, it is clear that SID_{APP} values are lower than they are for healthy volunteers.[91-93] The lower the baseline of the SID_{APP}, the greater the susceptibility to a subsequent acid load.[91-93]

SID has a powerful electrochemical effect on water dissociation, and hence on $[H^+]$. Both H^+ and OH^- behave as a weak cation and anion, respectively. Because practically all the cations in plasma are strong ions, except for H^+, only H^+ concentration can vary in response to changes in anions. On the other hand, there are several anions that are weak ions, and thus there are several options of anion molecules that can change their charges if cations change.[29,94] As the SID_{APP} increases (strong cations in excess over strong anions), plasma tends to become positively charged. Hence H^+, a weak cation, decreases and pH increases to maintain electrical neutrality, and alkalosis is produced. On the other hand, if the SID_{APP} decreases (strong anions in relative excess over strong cations), plasma tends to become negatively charged, more water is dissociated to have more H^+ for keeping electroneutrality, and acidosis is produced.[26,29,95] Changes in SID result from either a relative or an absolute change in strong ion concentrations. A change in the free water content alters the relative concentration of the strong ions, and hence a change in SID. If, as a result, $[Na^+]$, $[K^+]$, and $[C\lambda^-]$ decrease, the absolute figure for SID will decrease proportionately. Thus an excess of free water lowers SID and results in a tendency toward metabolic acidosis. In a similar manner, a free water deficit causes metabolic alkalosis by increasing the SID through a relative increase in concentration of all strong ions. Relative and absolute changes in sodium concentration primarily result from osmoregulation, and thus they are reflective of changes in free water. The remaining strong cations, potassium, magnesium, and calcium, as they are tightly regulated by the body for other functions (coagulation, membrane excitability, neuromuscular plates, muscle contraction, etc.), do not vary significantly enough to directly cause alterations in acid-base balance.[61] On the other hand, changes in strong anion concentrations are significant to acid-base status. Hypochloremia (from gastrointestinal or renal losses) is associated with metabolic alkalosis. Hyperchloremia (eg, from resuscitation with normal saline infusion) is associated with metabolic acidosis.

As the SID requires an actual change in the relative concentrations of strong cations or anions to be modified, the kidneys are the primary organs in charge of SID regulation by the body. As the kidneys can excrete only small amounts of strong ion into the urine each minute, several minutes to hours are required for achieving a significant change of the SID. Control of the kidney is important and precise because every chloride ion filtered and not reabsorbed increases the SID. Acid handling of the kidney has traditionally focused on H^+ excretion and the role of ammonia (NH_3) and ammonium (NH_4^+)as hydrogen ion carriers.[35,44,96,97] Because water provides an essentially infinite source of H^+, its excretion per se is possibly not as relevant as formerly taught. In fact, the H^+ net excretion by the kidney as water molecules is

larger than the excretion as NH_4^+. Therefore the purpose of renal NH_4^+ production is to allow the excretion of Cl^- without the excretion of Na^+ or K^+. Thus NH_4^+ is important to systemic acid-base balance, not only for its role as an H^+ carrier or for its direct action in the plasma (normal $[NH_4^+]$ is <0.01 mmol/L) but because it allows a safe excretion of Cl^-.[29,97]

Additional strong anions may become significant (hyperlactatemia, sulfate, ketoacids, anions from Krebs cycle, etc.), appear de novo in disease states (several organic acids from inborn errors of metabolism), or enter the body as medications or toxic substances (salicylates, certain β-lactam antibiotics, etc.). They may eventually influence the value of SID_{APP}.[91-93,98,99] Because it is usually not possible to have a direct measure of $[XA^-]$ at bedside (with the exception of lactate), it is not always convenient to use SID_{APP} for assessing the strong ions status, particularly among the most critically ill patients. According to the principle of electroneutrality (Eq. 16), blood plasma cannot be charged, so there should be remaining negative charges balancing the excess of plasma strong cations in relation to the strong anions, which is the origin of SID_{APP}. These balancing negative charges do not come from other strong anions but from weak anions. SID_{APP} (Eqs. 19A and 19B) does not take into account the role of weak acids (HCO_3^-, albumin, and dihydrogen phosphate), which have concentrations in plasma large enough that their changes can produce significant acid disturbance. This is expressed through the calculation of the effective strong ion difference (SIDe):

$$\begin{aligned} SID_{EFF} &= 1000 \times 2.46 \times 10^{-11} \times PCO_2/10^{-pH} + [\text{albumin in g/dL}] \\ &\quad \times (0.123 \times pH - 0.631) + [PO_4 \text{ in mmol/L}] \\ &\quad \times (0.309 \times pH - 0.469) \end{aligned} \qquad \textbf{(Eq. 20)}$$

The original calculation proposed by Figge and colleagues[94,100] is complex and cumbersome for use in the clinical arena.[86,101-103] Several simplifications have been proposed.[8,45,86,104,105] Although there is no consensus and no data about what equation should be used, the following is one of the most frequently cited[106]:

$$\begin{aligned} &\{[HCO_3^-] + (\text{albumin} \times 0.123 \times [pH - 0.631]) \\ &\quad + \text{phosphate} \times 0.309 \times [pH - 0.469]\} \end{aligned} \qquad \textbf{(Eq. 21)}$$

where HCO_3^- is in mEq/L, albumin in g/L, and phosphate in mmol/L.

The SID_{EFF} formula quantitatively accounts for the contribution of weak acids to the electrical charge equilibrium in plasma. Once weak acids are quantitatively taken into account, the SID_{APP} to SID_{EFF} difference should equal zero (electrical charge neutrality) unless there are unmeasured charges to explain this ion gap.

Strong Ion Gap

In the healthy individual, SID_{APP} and SID_{EFF} are nearly identical and therefore are adequate estimates of the true SID and of the acid-base status.[29,78] However, in

disease states, this might not be true, as several unmeasured ions (mainly anions) may be present in plasma.[99,100,107-109] To address this situation, Jones[110] and Figge[98] independently proposed a similar scanning tool. Kellum and coworkers coined the term *strong ion gap (SIG)* to name this new tool,[111,112] a far from ideal term, because the unmeasured anions creating the gap can be either strong or weak[99,100,113] (see Table 76.5). Nowadays, a modern clinical lab can easily measure all the components of the SID_{APP} and SID_{EFF} equations, including lactate. As a result, $[XA^-]$ is easily approximated through SIG, which is calculated as follows:

$$SIG = SID_{APP} - SID_{EFF} \tag{Eq. 22}$$

By convention, SIG is positive when unmeasured anions exceed unmeasured cations (acidosis) and negative when unmeasured cations exceed unmeasured anions (alkalosis). In ideal theoretic conditions, it would be possible for the sum of strong cations and weak anions to cancel each other out, with a SIG equal to zero. In the real world, most SIGs are positive (anions > cations). The use of SIG is advocated in situations in which SID_{APP} and SID_{EFF} are not equal.[111,112] SIG different to zero may also be explained, at least in part, by the difference between *ionic molar concentration* (the basis for SID_{APP}) and *ionic activity* itself (the basis for SID_{EFF}). Ionic molar concentration is a measure of the actual number of ions in solution. On the contrary, ionic activity is a measure of the effective concentration of electrolytes that results from the charge interaction on dissociated species. The difference between ionic concentration and ionic activity is important because the molar concentration of any electrolyte will not affect the molar concentration of any other electrolyte. But ionic activities are mutually interactive. The principle of electrical neutrality only refers to the latter.[33] Both SID_{EFF} and SIG have been evaluated as prognostic markers in both children and adults. Both indexes have shown good predictive capability in most publications, but there is not universal agreement regarding its clinical usefulness.[8,61,85,101,114-123] If one would like to increase the precision of SIG, one should include as many factors as possible in the calculation of SID_{EFF}. However, a theoretic downside is that each additional analyte may increase imprecision,[113] and the calculations remain cumbersome in the clinical arena, but appropriate online calculators are available. Perhaps the main advantage of SIG is that it remains stable with severe pH stress (<6.85, >7.55), a clear advantage when compared to AG. The well-known AG increase parallel with pH has been related to altered albumin and phosphate dissociation in extremes of pH.[111]

Nonvolatile Weak Acids (Albumin and Phosphate)

Unlike H_2CO_3 through its conversion to CO_2, nonvolatile weak acids cannot be eliminated by respiration; most have a pK_a near the physiologic pH of 7.4. Therefore weak acids (A_{TOT}), as opposed to strong ions, can exist at physiologic pH as dissociated (A^-) or associated with a proton (AH). Weak acids are often referred to as buffers. The concentration of each one of these weak acids is the sum of its dissociated and undissociated forms:

$$A_{TOT} = AH + A^{-} \quad \textbf{(Eq. 23)}$$

The two nonvolatile weak acids with great enough concentrations in plasma to have an influence on acid-base status are albumin and inorganic phosphate, the latter having a minor effect. Although the loss of weak acid (A_{TOT}) from the plasma space is an alkalinizing process, there is no evidence that the body regulates A_{TOT} directly to maintain acid-base balance. For example, there is no evidence that clinicians should treat hypoalbuminemia as an acid-base derangement.[29] What is observed in hypoalbuminemic patients is that SID tends to be decreased in relation to healthy individuals. This means that the kidney has already compensated for the alkalinizing effect of hypoalbuminemia by increasing the reabsorption of Cl^{-}, increasing plasma strong anions and reducing the SID.[29] There remains controversy about whether or not albumin fluctuations provoke a change in the pH.[41,120] Although albumin is a prominent acid in serum, there is no documented respiratory compensation with changes in albumin concentration.[124]

Strong Ions and Urinary Anion Gap

A urinary anion gap (uGap) was described some time ago to compare the loss of measured strong cations (sodium and potassium) with the loss of chloride.[125] This urinary gap has also been designated by some authors as the *urine strong ion difference (uSID)*[29,35] or the *urinary net charge gap*[122]:

$$uGap = uSID = [uNa^{+} + uK^{+}] - [uCl^{-}] \quad \textbf{(Eq. 24)}$$

Certainly, sodium, potassium, and chloride are all strong ions, so the name is, at least, functionally correct. As its serum analog, the uSID estimates the unmeasured urinary ions. The excretion patterns of urinary electrolytes reflect the ability of the kidney to counteract nonrenal acid-base disorders. The capacity of the kidney to excrete ammonium chloride in acidosis allows for the elimination of anions with conservation of sodium for volume and potassium for potassium balance. This potassium-sparing effect of urinary ammonium is evident in the hypokalemic stimulation of ammoniagenesis. The traditional physiologic approach interprets the urine electrolytes to deduce the presence of ammonium and bicarbonate with less emphasis on the strong ion pathogenesis of acid-base disorders. The physicochemical model emphasizes the relative losses of the actual measured quantities to determine the cause of the disturbance. Both perspectives are complementary and enlightening for the critical care field.[96,97,122]

In terms of quantity, the most important unmeasured urinary strong anion (Ur^{-}) is SO_4^{2-} (derived from the metabolism of sulfur amino acids), whereas the most important unmeasured cation (Ur^{+}) is ammonium (NH_4^{+}). In physiologically normal conditions, uSID must equal the plasmatic SID_{APP} (ie, 38-42 mEq/L). When a strong ion enters the plasma (eg, lactate, or a chloride load), plasmatic SID obviously will decrease. Normal kidneys will react by increasing its excretion of chloride, thereby decreasing the plasma chloride concentration, whereas $[Na^{+}]$ and $[K^{+}]$ must be maintained within normal ranges. This is accomplished by increasing the excretion rate of NH_4^{+}, which is the more efficient way for increasing chloride elimination

without losing sodium or potassium.[96,97] The increased excretion of chloride will decrease the uSID.[103] Thus a negative value for the uSID indicates the presence of the unmeasured cation, ammonium (excretion of ammonium chloride). The loss of ammonium chloride in the urine of a patient with metabolic acidosis is a normal renal response to nonrenal causes of metabolic acidosis, because the losses of urinary chloride result in an increased plasma strong ion difference, which in turn permits the formation of more bicarbonate. However, in the situation of a metabolic alkalosis, a relative excess of chloride in the urine strongly suggests that the losses of urinary chloride are causally related to the metabolic alkalosis process by increasing the plasma strong ion difference. This is a typical situation in patients receiving furosemide, which inhibits the sodium-potassium-chloride cotransporter in the thin ascending limb of the loop of Henle. This causes proportionately more chloride than sodium loss in the urine. Thus there is a direct explanation for the hypochloremic metabolic alkalosis in such cases. Inhibition of the sodium-chloride cotransporter of the distal tubule by thiazides is another cause of metabolic alkalosis because of the proportionally greater loss of chloride than sodium from the extracellular fluid. In addition to chloride wasting by diuretics, many hereditary disorders of sodium and chloride transport by the renal tubules (the so-called channelopathies) may cause acid-base disorders.

A positive value for the uSID indicates excretion of an unmeasured anion. The lost, unmeasured anion may be bicarbonate or nonbicarbonate anions such as ketones, lactate, and hippurate among persons who sniff glue.[122,126] This loss of anions will decrease the plasma strong ion difference and acidify the extracellular fluid as the process returns chloride to the circulation. If the urinary clearance of these nonchloride anions is high enough that they do not accumulate as a plasma anion gap, then the hyperchloremia may be mistaken for renal tubular acidosis.[125] Without those nonbicarbonate anions, metabolic acidosis with the loss of urinary sodium and potassium and retention of chloride (the positive-charge gap) will result in a decreased plasma strong ion difference, constituting a renal cause of acidosis (eg, carbonic anhydrase inhibition by acetazolamide, or renal tubular acidosis). If metabolic alkalosis is present, a positive urinary gap suggests that the renal loss of strong cations (sodium and potassium) and conservation of chloride will try to acidify the extracellular fluid because of a decrease in the plasma strong ion difference and in the bicarbonate concentration.[122] In the presence of volume and potassium depletion, metabolic alkalosis is maintained, not corrected, by the kidneys.[127] Low extracellular fluid volume and low blood pressure increase angiotensin II and aldosterone levels. Increased sodium reabsorption through proximal tubular sodium-hydrogen exchange and the collecting-duct sodium channel, accompanied by hydrogen secretion by the hydrogen ATPase and the potassium-hydrogen ATPase, in turn increases bicarbonate reabsorption until the urinary pH decreases as it becomes free of bicarbonate. This paradoxical aciduria in the middle of alkalemia is evidence that blood pH depends on strong ion balance. The alkalemia will be corrected only with sufficient replacement of sodium, chloride, and potassium.[122]

In respiratory conditions, the $PaCO_2$ is the initial abnormality leading to sudden changes in pH, with little change in strong ion concentrations. Over time, however, the change in the level of chloride and reciprocal changes in the level of bicarbonate are the major factors that allow pH to return toward normal values. The

hyperchloremic renal compensation for respiratory alkalosis is the excretion of filtered sodium and potassium with bicarbonate, because low $PaCO_2$ decreases proximal and distal hydrogen secretion. As the plasma strong ion difference decreases, the plasma bicarbonate concentration will decrease. In respiratory acidosis, high $PaCO_2$ increases production of ammonia by the kidney, and the excretion of ammonium chloride with a negative uSID results in hypochloremia, an increased plasma strong ion difference, and an elevated plasma bicarbonate concentration. The elevated $PaCO_2$ increases the renal reabsorption of sodium and bicarbonate, so the compensation is maintained. If the $PaCO_2$ is abruptly lowered through mechanical ventilation, the compensatory response shifts to posthypercapnic hypochloremic metabolic alkalosis, which will not resolve until the chloride that is lost as ammonium chloride is replenished.[96,122]

In addition to the kidney, both the liver and the gastrointestinal tract may have an influence on SID. In the stomach, Cl^- is pumped out of the plasma and into the lumen, reducing the SID (and pH) of the gastric fluids, but increasing the SID (and pH) in the plasma side ("alkaline tide"), because of the exit of Cl^- to the stomach. However, only a slight change in plasma pH becomes evident, because Cl^- is reabsorbed in the duodenum just as fast as it was pumped out. However, if gastric secretions are removed, either by vomiting or suction catheter, the SID will progressively increase, as will the pH, as a result of Cl^- loss. Although H^+ is excreted as HCl, it is also lost with every water molecule that exits the body. When the body loses Cl^-, a strong ion, without also losing a strong cation, SID is increased and therefore $[H^+]$ is decreased and alkalosis ensues. When H^+ is excreted as H_2O rather than as HCl, there is no change in SID, and consequently there is no change in $[H^+]$. It remains unknown whether the gastrointestinal tract, the liver, and the pancreas are capable of compensatory actions for regulating strong ion uptake.[128]

Conceptual and Practical Integration of the Tools for Assessing Acid-Base Balance

Three methods are currently applied to measure acid-base disorders: the bicarbonate/CO_2 physiologic approach, the base excess approach, and the physicochemical approach. The first two approaches, which are based on the analysis of plasma concentration of bicarbonate and standard base excess (SBE), and further by the use of plasma anion gap (AG), are the most widely used methods to evaluate the metabolic component of acid-base disturbances. One advantage of these methods is that they are easy to understand and apply in common clinical situations. However, the SBE is a calculated figure derived from $PaCO_2$ and arterial pH, but reliance on its use alone to quantify metabolic disturbances has a number of pitfalls. First, it cannot identify whether an acidosis is due to increased tissue acids, hyperchloremia, or a combination of both. Second, its calculation assumes normal plasma protein, which may limit its accuracy in critically ill patients.[61,98] AG is grossly underestimated in the presence of hypoalbuminemia, which is a frequent occurrence in critically ill patients.[78] An alternative evaluation is the mathematical model based on physiochemical principles described by Stewart[32] and modified by Figge.[78,94,100] This method allows the clinician to quantify individual components of

acid-base abnormalities and provides insight into their pathogenesis.[61] Many studies have shown that this approach, compared to the traditional approaches, works best to identify acid-base disorders in the population of critically ill patients.[129,130] Nevertheless, Stewart's approach is a time-consuming method and unsuitable at the bedside.

Table 76.5 presents an overview of the available tools for the assessment of the metabolic component of acid-base balance. Table 76.6 summarizes the classification of acid-base derangements according with the tools and assumptions of the different approaches.

TABLE 76.6

Classification of Acid-Base Derangements According to Several Approaches

	BICARBONATE-CENTERED APPROACHES		PHYSICOCHEMICAL APPROACH
Derangement	**Bicarbonate Rules of Thumb**	**Base Excess/Deficit (BE)**	**PCO_2/SID-SIG/A_{TOT}**
Metabolic Acidosis			
—Primary problem	↓ [HCO_3^-] and ↓ pH	Base deficit (-BE, -SBE), ↓ pH	↓ SID_{EFF}, and ↓pH
—Secondary response	↓ PCO_2[a]	↓ PCO_2[a]	↓ PCO_2[a]
Unmeasured anions	Needed[b] Normal AG = hyperchloremic acidosis High AG = normochloremic acidosis	Needed[b] Normal AG = hyperchloremic acidosis High AG = normochloremic acidosis	Included by default SID acidosis (↓ SID_{APP} = ↓ SID_{EFF}), so SIG = 0 (*equivalent to* hyperchloremic acidosis) SIG acidosis (SID_{APP}, no change ↓ SID_{EFF}) so SIG = ↑ (*equivalent to* normochloremic acidosis)
Effect of non HCO_3^- plasma weak acids mainly albumin	Not assessed	Not assessed	↑ primary in A_{TOT} ("hyperalbuminemic acidosis")
Metabolic Alkalosis			
—Primary problem	↑ [HCO_3^-] and pH	Primary base excess (+BE, +SBE), ↑ pH	↑ primary SID_{APP} and SID_{EFF} ↑ pH (SID alkalosis)
—Secondary response	↑ PCO_2	↑ in PCO_2	Not contemplated
Effect of non-HCO_3^- plasma weak acids mainly albumin	Not assessed	Not assessed	↓ Primary in A_{TOT} ("hypoalbuminemic alkalosis")
Respiratory Acidosis			
—Primary problem	↑ in PCO_2 and ↓ pH	↑ PCO_2 and ↓ pH	↑ PCO_2 and ↓ pH
—Secondary response	↑ [HCO_3^-] Acute or chronic	Acute: ΔSBE = 0 Chronic: +SBE	Not considered
Respiratory Alkalosis			
—Primary problem	↓ PCO_2 and ↑ pH	↓ PCO_2 and ↑ pH	↓ PCO_2 and ↑ pH
—Secondary response	↓ [HCO_3^-] Acute or chronic	Acute: ΔSBE = 0 Chronic: ΔSBE = −SBE	Not considered

[a]Always adjust PCO_2 values to the height above sea level of your city. Empirical rules for compensation are minimally affected.

[b]Anion gap correction for albumin and lactate not usually performed. It is now recommended to do so (see text for details).

Acute, minutes to hours; *AG*, anion gap; *A_{TOT}*, total anions in plasma (non HCO_3^- weak acids); *BE*, base excess; *chronic*, several days or longer; ↓, decrease; *HCO_3^-*, bicarbonate; ↑, increase; *PCO_2*, carbon dioxide partial pressure (always arterial for calculating deltas); *SBE*, standard base excess; *SID_{APP}*, strong ion difference (apparent); *SID_{EFF}*, strong ion difference (effective); *SIG*, strong ion gap.

Adapted from Seifter JL. Integration of acid-base and electrolyte disorders. N Engl J Med 2014;371:1821-1831; Adrogué HJ, Gennari FJ, Galla JH, Madias NE. Assessing acid-base disorders. Kidney Int 2009;76:1239-1247.

Despite apparent differences between the traditional bicarbonate-centered and the physicochemical approaches to the acid-base physiology, they are complementary. At the present time, most clinicians accept a bimodal categorization of acid-base disorders as either *respiratory* or *metabolic,* but after more than a century, there is still no universally agreed upon method of defining and quantifying the metabolic component. This is perhaps not surprising, if one considers not only the conceptual controversies but the human passion rather than rationale involved in this controversy.[8,36,41,49,72-75] For example, Stewart's classification of HCO_3^- and H^+ as *dependent* variables is felt to be a sacrilege by many physiologists as well as clinicians.[8,41,49] All available methods (bicarbonate, SBE, AG, and Stewart's) have been heavily criticized,[41,131-133] and all of them have been advocated as the gold standard, whereas others claim that they all yield virtually identical results.[41,65,134] Perhaps the major merit of the physicochemical approach is that it became attractive to the intensivist because it offered a comprehensive explanation for some metabolic derangements associated with ionic alterations, such as the so-called hyperchloremic acidosis. The evidence connecting acid-base balance with electrolyte balance is apparent at the cellular level (ion transporters, their stoichiometric balance, and the hormones that regulate them) and in clinical practice. The fact that transporters often couple a strong ion such as sodium or potassium with hydrogen, or chloride with bicarbonate, suggests an ultimate coherence between the two systems.[59,122,135,136] Since the 1920s and 1930s, Peters and Van Slyke defined acid-base balance in the blood as the chemical state resulting from the balance between cations and anions.[24] This means that metabolic acid-base disorders can be visualized as the predicted consequences of a primary fluid and electrolyte imbalance. In keeping with the laws of electroneutrality, all charged species must balance. This requires that any change in the concentration of one of the charged variables (the strong ion difference) must be matched by a change in the concentration of another charged species. Thus all metabolic acid-base disorders are associated with either a change in the concentration of sodium, potassium, calcium, chloride, hydrogen, phosphate, or albumin or a change in the anion gap.[122] Therefore the first step in understanding how an acid-base disorder develops is to know or assume the specific electrolyte content of any gained fluids (eg, intravenous fluids) or lost fluids (eg, gastrointestinal fluids, sweat, or urinary fluids). Because the normal concentration ratio of sodium to chloride in extracellular fluid is approximately 140 : 100, an increase in the sodium level, a decrease in the chloride level, or both will increase the strong ion difference and the bicarbonate concentration will increase (metabolic alkalosis), according to electroneutrality requirements.[137] When the strong ion difference decreases, pH and the bicarbonate level will decrease (metabolic acidosis). Any developed difference in the ionic charge, or strong ion difference, determines the bicarbonate concentration. The traditional acid-base approach tacitly overlaps with aspects of the strong ion theory (Table 76.7). Both experimental and clinical observations can be explained with the use of either model. Yet the physicochemical model is useful in revealing individual processes in the development of an acid-base disturbance because it associates the abnormality with specific electrolyte disturbances.[26,122]

TABLE 76.7

Integrated Clinical Approach to Acid-Base Derangements in Critical Care

Step	1. Inquiry	2. Assessment	3. Action
1	Clinical suspicion of metabolic derangement?	No CVC: Check peripheral venous blood sample for tCO_2 and pH Already in PICU or ER? Direct to action!	Obtain ABG if peripheral tCO_2 or pH are abnormal or if clinical picture justifies it
2	pH?	pH <7.35 → acidosis with acidemia pH >7.45 → alkalosis with alkalemia If pH = 735-7.45, unbalance is not yet ruled out	Check PCO_2 and SBE
3	Respiratory side?	PCO_2 and pH have moved in opposite directions	There is a respiratory problem Use traditional approaches (bicarbonate rules of the thumb or SBE) (see Table 76.6)
4	Metabolic side?	PCO_2 and pH have moved in the same direction	There is a metabolic problem with respiratory compensation
		OR	
		SBE <-3?	There is a metabolic acidosis
		OR	
		Clinical suspicion of ACIDOSIS in spite of inconclusive pH, PCO_2, SBE (and HCO_3^-)?	Check lactate and albumin Calculate $AG_{CORRLACT}$ Will need Na^+ and Cl^-
5	Anions?	Use surrogates of SID and SIG:	
		a. For SID_{APP} use $[Na^+] - [Cl^-]$	a. $[Na^+] - [Cl^-]$ – <42.7 mEq/L = SID acidosis (hyperchloremic acidosis) – >47.5 mEq/L = SID alkalosis (hypochloremic alkalosis)
		b. For SIG use $AG_{CORRLACT}$	b. $AG_{CORRLACT}$ >8 mEq/L = SIG acidosis (normochloremic or gap acidosis)
		c. Lactate >2 mmol/l or >50% of SBE?	c. Predominant lactic metabolic acidosis

d. Lactate <2 mmol/l; normal Cl^-?	d. Check A_{TOT} and full calculation of SID_{APP}, SID_{EFF}, and SIG		
e. SIG >50% of SBE?	e. Yes: Predominant SIG metabolic acidosis (normochloremic acidosis, Gap acidosis) No: Predominant SID metabolic acidosis (hyperchloremic acidosis, nonGap acidosis) IF no single anion group accounts >50% of SBE, there is probably a mixed disorder		
6	Compensations?	Use bicarbonate or SBE observational patterns	Warnings! 1. Under ventilatory support or with neural or respiratory problems, respiratory compensation can be modified or not completed 2. Hypoalbuminemia is common in PICU. Extreme low levels (<2 g/dl) may modify AG and, potentially, pH 3. Diuretics may modify metabolic response to acidosis through Na^+ and Cl^- losses in urine; uGap can be useful to assess renal response
7	Final analysis?	Define the A-B derangement: Simple versus mixed? Compensated versus noncompensated?	Construct differential diagnosis of the possible underlying causes
8	Treatment?	Focus on the underlying disorder Compensate every electrolyte unbalance Consider bicarbonate and mechanical ventilation in severe cases (pH <7.1)	Follow PALS guidelines Reassessment according to progress

Note: Please read each line from left to right (Inquiry → Assessment → Action) before proceeding to the next step, starting again from the left side, in the same order.

ABG, arterial blood gas; *$AG_{CORRLACT}$*, anion gap corrected for albumin and lactate; *A_{TOT}*, total nonbicarbonate plasma anions (weak acids); *CVC*, central venous catheter; *HCO_3^-*, bicarbonate; *Na^+ and Cl^-*, Na^+ and Cl^- blood levels; *PALS*, pediatric advanced life support; *PCO_2*, carbon dioxide partial pressure; *SBE*, standard base excess; *SID_{APP}*, strong ion difference (apparent); *SID_{EFF}*, strong ion difference (effective); *SIG*, strong ion gap; *tCO_2*, total CO_2; *uGap*, urinary anion gap.

(See text for calculation of $AG_{CORRLACT}$, SID_{APP}, SID_{EFF}, SIG, uGap; for bicarbonate and SBE rules of thumb, see Tables 76.2, 76.3, and 76.6.)

The major inconvenience of the physicochemical approach is the complexity and potential inaccuracies in correctly calculating SID_{APP}, SID_{EFF}, and SIG.[8,41,49,79] Nevertheless, because the Stewart method evaluates all major serum ions, and many of these variables are measured daily in the intensive care setting, many critical care practitioners, particularly in the adult field, have adopted this concept to describe complex acid-base derangements.[104] To help simplify things, there are now surrogates of some of the complex physicochemical equations. With PCO_2 analysis and the Henderson-Hasselbalch equation, it is possible to describe and quantify the respiratory side of the acid-base balance. To describe the metabolic side requires more complex analysis. The traditional tools for approaching the metabolic side, AG

and SBE, now have been augmented by Stewart's physical-chemical concepts, with improved performance.[84-86,138,139] In spite of the apparent differences among these three methods, they all share a common theoretic foundation based on the principle of electroneutrality and the role of plasma weak acids (Fig. 76.1). Prompt identification of unmeasured anions is essential in any acid-base analysis in the critical care setting, because mortality associated with strong ion acidosis, both lactic and nonlactic, is significantly higher than that associated with hyperchloremic acidosis (56%, 39%, and 29%, respectively).[1,86,119] Accordingly elevated unmeasured anion is a predictor of mortality. The best diagnostic tools for the early detection of the unmeasured anions (XA^-) are AG_{CORR} (not AG), SIG, and physicochemical adjusted SBE (also known as partitioned SBE or the BE gap).[86,139]

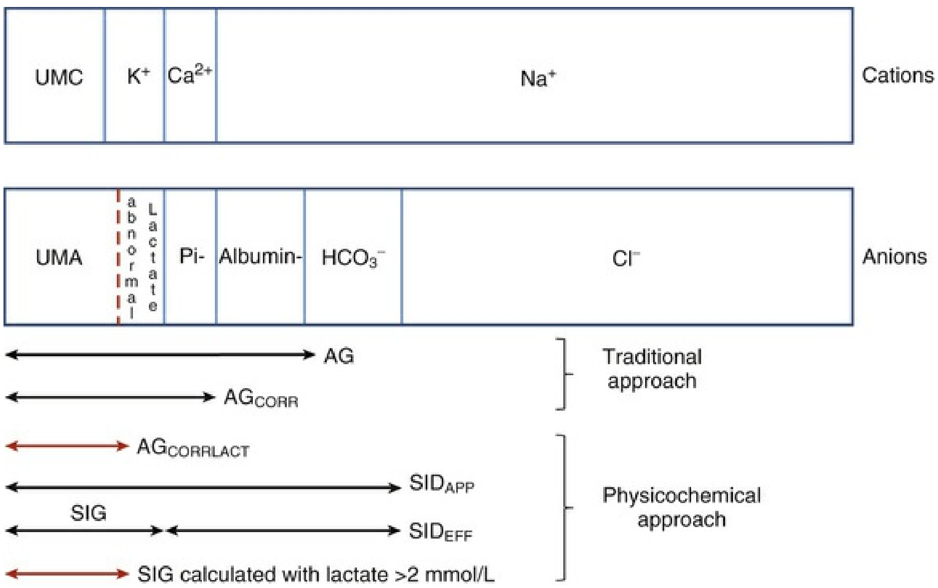

FIG. 76.1 Indexes used for detection of unmeasued anions in both approaches: traditional and physicochemical. If lactate levels are higher than normal, then its value should be added to SID_{EFF} and included in the calculation of SIG. When this is the case, note that SIG and $AG_{CORRLACT}$ are very similar, as ocurrs with SID_{APP} and the $[Na^+] - [Cl^-]$ difference. *AG*, Anion Gap; *AG_{CORR}*, Anion Gap corrected for albumin; *Ca^{2+}*, Calcium (ionic); *Cl^-*, Chloride; *K^+*, Potassium; *Na^+*, Sodium; *Pi^-*, Inorganic phosphate; *SID_{APP}*, Strong Ion Difference (apparent); *SID_{EFF}*, Stron Ion Difference (effective); *SIG*, Strong Ion Gap; *UMA*, Unmeasured or unidentified anions; *UMC*, Unmeasured or unidentified cations.

Surrogates of Strong Ion Difference and Strong Ion Gap: Corrected Anion Gap and Na^+-Cl^- Difference

In addition to correcting the anion gap for hypoalbuminemia (AG_{CORR}) additional corrections may be warranted.[83] Hyperchloremic acidosis may go undetected with the AG_{CORR} method, in the setting of a dilutional alkalosis.[86] Hence a "corrected" value of chloride would theoretically be needed. However, the very concept of "corrected chloride" is criticized by some authors, as no other element of AG

equation (nor of SID or SIG's) is "corrected" for water excess or deficit,[113,139] and because the "sodium correction" of the chloride assumes a fixed sodium-chloride relationship that does not occur in vivo.[140-143] Hence there is no uniform acceptance of "corrected" Cl^- values for calculating AG. On the other hand, in order to avoid [lactate$^-$] influence on AG_{CORR} that could mask the detection of other unmeasured anions, it has been suggested that AG should be corrected not only for albumin but also for lactate. This is simply made by substracting the serum lactate concentration (in mmol/L) from the already albumin-corrected AG (Eq. 18A and 18B)

$$AG_{CORRLACT} = \text{Albumin-corrected AG} - [\text{lactate (mmol/L)}] \qquad \textbf{(Eq. 25)}$$

This albumin- and lactate-corrected AG ($AG_{CORRLACT}$) seems to correlate well with the SIG.[108,140,144] $AG_{CORRLACT}$ is an easy bedside measurement that may approximate the SIG in critically ill patients. Using uncorrected value AG in critically ill patients, is often unwise given the high prevalence of hypoalbuminemia. If AG needs to be determined, it should be corrected for hypoalbuminemia and lactate as appropriate (AG_{CORR} or $AG_{CORRLACT}$).[83-88,138,139]

As sodium and chloride are the ions with the highest plasma concentration, the difference between them ($[Na^+]–[Cl^-]$) can be used as surrogate for the apparent SID.[85,145,146] In a cohort of 341 critically ill patients, researchers demonstrated that the difference between sodium and chloride ($[Na^+] – [Cl^-]$) and anion gap corrected for albumin and lactate ($AG_{CORRLACT}$) can be used as apparent strong ion difference (SID_{APP}) and strong ion gap (SIG) surrogates, respectively.[106] Substitution of $[Na^+] – [Cl^-]$ and $AG_{CORRLACT}$ for SAD_{APP} and SIG, respectively, simplifies the diagnosis and management of acid-base disorders in critically ill patients. Similarly, there have been suggestions for improving the SBE. Partitioned SBE, or *base excess gap*, is an attempt to combine the approaches of Siggaard-Andersen and Stewart in a kind of physicochemical adjusted SBE, which seeks to quantify the metabolic component of acid-base disorders.

Based on an analysis of Stewart's model, Gilfix[147] proposed that only four conditions may create nonrespiratory acid-base disturbances, which are as follows: (1) free water deficit or excess (BE_{fw}), as determined by changes in sodium concentration; (2) changes in chloride concentration (first corrected for the free water effect) (BE_{Cl}); (3) changes in protein charges, mainly albumin (BE_{alb}); and (4) the presence of organic unmeasured anions (BE_{XA}). Accordingly SBE may be "partitioned" (using abridged Stewart equations)[144,148-150] into four "physical-chemical" segments. Gilfix showed that the lab-reported SBE, or total SBE (SBE_{TOTAL}) should equal the sum of the BE for each one of the four conditions. This approach has received some criticism for small but potentially important inaccuracies.[113] In spite of these physiologic and conceptual caveats, this approach was first tested in children in a pediatric intensive care unit in 1999, with apparent success.[144] Reported successful applications in mortality prediction, and classification of acidosis in several settings, including sepsis and septic shock, cardiac surgery, diabetic ketoacidosis, and others, soon followed.[8] Unfortunately, lack of standardization in regard to the formulas employed for BE partitioning has been associated with large

and clinically important discrepancies between several studies.[139,147-150]

Tools of the traditional approach are the first line for choice assessing respiratory acid-base disturbances and for the initial appraisal of the metabolic problems (bicarbonate and SBE) (see Table 76.7). For in-depth metabolic analysis, the proved surrogates of SID_{APP} and SIG, $AG_{CORRLACT}$ and the difference $[Na^+] - [Cl^-]$, are recommended. At present time, SBE partitioning is not recommended as a routine approximation to acid-base metabolic derangements. The advantage of this approach is that it allows the clinician to detect complex, mixed acid-base derangements in the critical care setting. This physicochemical approach yielded the additional diagnosis of metabolic disorders in 33.7% of patients in one single-center adult study.[151] However, it remains unclear if the identification of these additional acid-base disorders translates into new and otherwise unanticipated therapeutic interventions in these patients.[120,134] Nevertheless, the physical-chemical approach undoubtedly improves biological plausibility regarding the physiopathologic derangement behind the patient's acid-base status.[31]

New Insights for Old Problems

The classical acid-base approach yielded commonsense explanations for some acid-base disturbances often seen in the clinical arena. For example, it is said that the metabolic alkalosis seen with severe emesis or nasogastric tube losses is due to a *loss of H^+*, that the metabolic acidosis seen in persistent postpyloric fluid losses is due to a *loss of bicarbonate,* that an acidosis caused by large volume fluid administration is caused by *dilution of bicarbonate,* and that sodium bicarbonate ($NaHCO_3$) therapy corrects metabolic acidosis by contributing bicarbonate ion (HCO_3^-) to the body. These time-honored explanations have been challenged by the new view of the acid-base balance, in which water dissociation and the ionic composition of body fluids represent a core principle.[28,29,33,122] According to these new concepts, pH has no direct relationship with any total body direct loss or gain of H^+ or HCO_3^- but rather reflects the change of the proportion in cations and anions (strong ions and weak acids), their effect on water dissociation, and possibly other mechanisms controlling ion flux through cell membranes.[122] Kidney function, and possibly other organs such as liver, also participates in the control of the pH and HCO_3^-, but the fundamental physicochemical principles are the same.

For example, it is well recognized that the acute expansion of extracellular volume with normal saline solution (sodium chloride [NaCl] 0.9%) or with any unbalanced synthetic colloid solution (6% hydroxyethyl starch solution or 4% gelatin) may result in hyperchloremic acidosis.[148,152-160] The understanding of this condition has improved through the physicochemical comprehension of the acid-base equilibrium: Saline causes acidosis not through dilution of bicarbonate but rather by its Cl^- content, which increases the anion chloride out of proportion of the cation sodium, which decreases the SID_{APP} and increases water dissociation and $[H^+]$.[152-157] This occurs despite equal amounts of Na^+ and Cl^- in saline solution, because in plasma sodium and chloride concentrations are different. Therefore when large amounts of NaCl in solution are infused, they have a proportionally greater effect on total body chloride than on total body sodium.

Elevated gastric fluid losses seen with severe emesis or nasogastric drainage are

the opposite example: The loss of high amounts of chloride leads to an increase in SID_{APP} and to alkalosis.[161] In addition to these examples, Stewart's water dissociation-centered model may provide new insight into the molecular biology and transport physiology of the renal tubule. For example, renal tubule acidosis (RTA) and Bartter syndrome may be redefined as *chloride channelopathies,* rather than disorders of net acid excretion.[104,122,162] In spite of the theoretic and mathematical certainties and the experimental and clinical evidence about the pertinence of the physicochemical approach, there is still no universal agreement about the clinical validity of these explanations or their clinical relevance.[121,163,164]

Clinical Problem: Does Abnormal pH Harm?

The clinician has been taught to fear abnormal pH, in particular acidemia. The rationale for this fear is that every protein in the body contains areas of both positive and negative charge, and hence they are electrochemically sensitive to the H^+ concentration of their environment.[8,33,41] Therefore a decrease or increase in pH beyond certain limits might be expected to have important detrimental effects on a host of bodily functions. In the critical care unit, acid-base disorders are often considered more important for what they tell the clinician about the patient than for any harm that is directly provoked by the acid-base imbalance. Several studies[29,165] have reinforced this concept because they showed that mortality was more closely related to the nature of acid-base disorders than to the magnitude of metabolic acidosis (estimated by partitioned SBE). Hyperlactatemia, more than the elevation of unmeasured anions ($AG_{CORRLACT}$, SID_{APP}, SIG) or SBE, is predictive of a poor outcome. Despite these reliable data from children with shock, it is generally accepted that acid-base derangement itself may cause harm in certain circumstances.[44,62,166] The obvious examples are the extreme conditions of pH (<7 or >7.7). It is also important, however, to consider how fast the acid-base derangement is evolving, along with the specific expected consequences of the alteration in specific patients. For example, in a patient who depends on vasopressors, vasodilation due to alkalosis—either respiratory and iatrogenic in origin for overzealous hand bagging of the patient or metabolic as a consequence of gastric fluid losses caused by a mechanically obstructed jejunum—can be catastrophic. Another typical example is the spontaneously breathing patient with metabolic acidosis who tries to compensate by increasing minute ventilation; if the patient gets tired, there is the possibility that hypoxemia will develop along with respiratory acidosis. In such cases, the underlying disorder must be treated, but one must also provide immediate treatment for the acid-base derangement itself.

The main expected physiologic effects of acidemia and alkalemia are as follows. Acidemia initially causes sympathetic and adrenal stimulation, an effect that is counterbalanced as the drop in pH becomes more and more severe, by a depressed responsiveness of adrenergic receptors to circulating catecholamines.[62,167-169] In isolated animal heart preparations and in isolated human ventricle muscle, there is no doubt that acidosis reduces contractile function.[169-171] The net influence of acidosis in the whole animal and in real patients, however, is more complicated to discern, and depending on the experimental or clinical model, it has been found that acidosis caused myocardial contractility to remain constant, decrease marginally, or transiently rise and then fall.[172] Hence the whole-body response to acidosis is less

clearly detrimental in real individuals. In many preclinical and clinical studies of patients undergoing permissive hypercapnia, a pH less than 7.2 was well tolerated,[173,174] as it is in youngsters with diabetic ketoacidosis,[175] children and adults with supercarbia,[176] and those with grand mal seizures.[177] Thus it is now clear that the effect of acidosis may differ according to type, magnitude, and time of onset.[119,176] Three types of extracellular acidosis—inorganic, respiratory, and lactic—may have disparate effects on left ventricular function in a model of isolated rabbit hearts.[178] Lactic acidosis caused a significant increase in the time to peak left ventricular pressure while retarding ventricular relaxation. This reinforced the concept that lactate ions have an independent and deleterious effect on myocardial function.[171,178] These findings make sense when they are extrapolated (with some reserve) to the clinical setting. Despite the frequent coincidence of clinical shock and metabolic acidosis, the striking discordance between the clinical course and outcome of patients with lactic acidosis compared with those who have ketoacidosis or ventilatory failure suggests that the low pH itself is important but not crucial for the presentation of the hemodynamic collapse of these patients.[168,172] Therefore the net effect on ventricular performance, heart rhythm, and vascular tone depends on the relative effects of many, sometimes competing, influences. In general terms, severe acidemia (pH <7.1-7.2)[1,35,44,62,171] is associated with decreased cardiac performance that provokes a drop in cardiac output, along with decreased vascular reactivity that manifests itself as arterial vasodilatation and venous constriction.[167] An important effect in the critical care setting is the marked increase in cerebral blood flow due to acute respiratory acidemia and its abrupt decrease with respiratory alkalosis (see also Chapters 60, 62 and 66).[179,180]

When PCO_2 acutely rises in excess of 70 mm Hg, loss of consciousness and seizures can be seen, probably due to the abrupt lowering of intracellular pH. Cultured lung epithelial cells exposed to cyclic stretch similar to that seen with mechanical ventilation produced a lactic acidosis that markedly enhanced the growth of *E. coli*.[181] In contrast, alkalinizing the pH abolished this effect. The demonstration that clinically relevant levels of metabolic acidosis enhance bacterial growth is of concern. However, in patients with acute respiratory distress syndrome (ARDS) treated with permissive hypercapnia mechanical ventilation, the gradual rise of the PCO_2 and the consequent drop of the pH are well tolerated in general terms, with no significant negative effects on systemic cardiac output, oxygen delivery, or vascular resistances, both pulmonary and systemic.[173,174] Actually, the hypercapnic acidosis has been shown to provide beneficial effects on pulmonary function by interacting with reactive oxygen species, the immune system, and the alveolar-capillary barrier.[180,181] However, evidence gathered through a multivariate analysis showed that changes in arterial pH, but not in positive end-expiratory pressure (PEEP) levels, were significantly correlated with impaired right ventricular function, whereas the left ventricle was spared.[182] Thus the net effect of respiratory acidemia to the patient, beneficial or detrimental, may be complex to elucidate. Other potential effects of acidemia include endogenous catecholamine, aldosterone, and parathyroid hormone stimulation; insulin resistance; increased free radical formation; increased protein degradation; gut barrier dysfunction; further respiratory depression; decreased sensorium; hyperkalemia; hypercalcemia; and hyperuricemia.[29,62] In regard to the effect of extracellular acidemia on inflammatory response and immune function, research has indicated that different acids produce

different effects, despite similar extracellular pH.[166]

When associated with severe alkalemia (pH >7.6), both metabolic and respiratory alkalosis lower blood pressure and cardiac output. The potential deleterious effects of this drop in systemic and regional blood flow may be aggravated by the increased hemoglobin oxygen affinity (shift to the left of the oxyhemoglobin dissociation curve), particularly in acute alkalosis. In chronic alkalemia this effect is counterbalanced by an increase in the 2,3-diphosphoglyceric acid concentration in red cells.[44] Cerebral circulation responds dramatically to alkalemia with marked vasoconstriction. Acute hyperventilation to PCO_2 of 20 mm Hg may drop cerebral blood flow to 50% of the basal flow. This effect has been used as an emergency management response to a rise in intracranial pressure, but it carries the risk of producing an excessive drop of blood flow in the most affected areas of the brain, with the increased possibility of ischemia and subsequent cerebral infarct (see also Chapter 66).[180] Because both metabolic and respiratory alkalemia may provoke abrupt transcellular membrane shifts of several electrolytes, mainly potassium and calcium, the net effect is an increase in neuromuscular irritability and excitability. Occurrence of seizures and cardiac arrhythmias has been reported, if pH exceeds 7.7.[161]

Therefore in terms of whether abnormal pH causes harm, the answer is complex: Potential harm always exists, but the occurrence of real damage depends on many factors, including the clinical setting of the patient; type of derangement (metabolic versus respiratory); timing of presentation (gradual versus sudden); renal, lung, and liver functional status; and type of metabolic acidosis and magnitude (mild, moderate, or severe). The answer regarding the possible benefit of acidosis is also complex, with similar caveats.

Blood Gases: Arterial, Central Venous, or Capillary Samples?

Considering the diversity of microcirculations and tissue metabolism throughout the body, the clinician must be aware that the value of a single arterial blood pH is limited, particularly as most functional proteins are intracellular.[168,172] There is a significant correlation in pH, PCO_2, partial pressure of oxygen (PO_2), SBE, and HCO_3^- among arterial, central venous, and capillary blood gases in healthy volunteers and in stable patients. However, in the presence of hypotension or shock, there is very poor or no correlation at all in PO_2 but some correlation of acid-base parameters.[183] Thus capillary and central venous blood gas measurements may be useful alternatives to arterial samples when an arterial line is not in place, in particular for acid-base evaluation.[184] However, in the severe circulatory failure setting, such as in decompensated, catecholamine-resistant septic shock and cardiac arrest, significant widening of the arteriovenous differences in pH, PCO_2, and lactate may occur. In the presence of severe hypoperfusion, hypercapnia and acidemia of peripheral tissues are best detected in central venous blood rather than in arterial blood samples.[185] In the setting of ARDS, the lungs may become important lactate producers, leading to significantly larger levels of lactate in the arterial blood gases than in the venous blood gases. Therefore both arterial and central venous blood samples are needed to assess acid-base status in patients with severe hemodynamic

compromise.

Metabolic Acidosis

The classical approach to metabolic acidosis is to classify the disorders as those with either *elevated AG* or *normal AG*, which continues to be a practical although not a pathophysiologically based classification (see Table 76.4). Using the physicochemical approach, metabolic acidosis can be classified as due to an *imbalance of strong ions* (decreased SID) or due to the presence of *abnormal nonvolatile weak acids* (increased A_{TOT}). In turn, decreased SID acidosis can be classified in two categories: that due to an excess of unmeasured anions (excess $[XA^-]$) (which grossly corresponds to the elevated AG acidosis) and that due to an excess of chloride or relative or absolute deficit of sodium-water excess (which corresponds to the non-AG acidosis) (see Tables 76.6 and 76.7). There appears to be a complex regulation of cations and anions (hence, for SID) for acid-base purposes, but no such mechanisms are known to control $[A_{TOT}]$. For this reason, there is no agreement as to whether or not changes in $[A_{TOT}]$ should be accepted as acid-base disorders, despite their influence on pH.[41] The classical approach will be used as the main frame for addressing metabolic acidoses, with additional information, mainly about pathophysiology, from the physicochemical approach.

Elevated Anion Gap Acidoses

These are a group of disorders in which there is the accumulation of an acidic anion. There are three clinically relevant examples: lactic acidosis, ketoacidosis, and acidosis secondary to the ingestion or administration of a toxin or drug.

Lactic Acidosis

The popular classification of hyperlactatemia as type A (*associated with or caused by* inadequate tissue oxygen delivery) or type B (adequate tissue oxygen delivery) is sustained because of its simplicity, even though it is not necessarily a reflection of the pathophysiologic mechanism underlying this alteration, as considerable overlap exists between types A and B[186] (Table 76.8). Type B was originally further subdivided into types B1, B2, and B3 acidoses: B1 associated with an underlying disease (eg diabetes mellitus, asthma, malignancies); B2 due to drugs or toxins (cyanide, metformin, epinephrine, etc.); and B3 due to inborn errors of metabolism. Type A seems to be the most frequent cause of lactic acidosis encountered in critically ill patients.[186,187]

TABLE 76.8

Causes of Metabolic Alkalosis in Critically Ill Patients

I. Chloride-Responsive (Decreased Urine $[Cl^-]$)[a]
A. Gastrointestinal Losses of Cl^-
1. Gastric drainage or persisting vomiting 2. Chloride-wasting acute diarrheas
B. Renal Losses of Cl^- and K^+
1. Diuretics (mainly acute use) 2. High dose of certain penicillin-derivative antibiotics

3. Posthypercapnia
II. Chloride-Resistant (Increased Urine [Cl^-])[b]
A. Excess Mineralocorticoid Activity: Ongoing Losses of K^+ and Cl^-
1. Primary and secondary hyperaldosteronism 2. Congenital adrenal hyperplasia (17α-hydroxylase or 11β-hydroxylase deficiency) 3. Cushing syndrome 4. Primary renin-secreting tumors 5. Steroid treatment
B. Genetic Renal Tubular Defects of Electrolyte Transport
1. Problem in chloride reabsorption a. Bartter and Gitelman syndromes 2. Defective epithelial sodium channel (decreased sodium elimination) b. Liddle syndrome
C. Drug-Induced Hypokalemic Alkalosis
1. Diuretics administered for prolonged time 2. High-dose glucocorticoids 3. Fludrocortisone 4. Aminoglycosides 5. Toxic effects of licorice *(Glycyrrhiza glabra)* 6. Ion exchange resin
D. Excess Cation (Alkali) Gain
1. Massive blood transfusion 2. Massive infusion of lactated Ringer solution 3. Parenteral hyperalimentation with excessive sodium acetate 4. Alkali ingestion/treatment and milk-alkali syndrome 5. Magnesium depletion
III. Miscellaneous Group (Variable Urine [Cl^-])[b]
A. Hypoproteinemia
B. Cystic Fibrosis
C. Congenital Chloride Diarrhea
D. Salt-Losing Nephropathy

[a]<20 mEq/L, usually <15 mE/L.

[b]>20 mEq/L, usually >40 mEq/L.

Among all metabolic acidoses, lactic acidosis in the pediatric intensive care unit (PICU) signals trouble, regardless of patient age.[187-193] Depending on the source, hyperlactatemia is defined as a lactate level between 2 and 5 mmol/L, whereas lactic acidosis is said to be present when the lactate level exceeds 5 mmol/L and the arterial pH is less than 7.35.[194] The lower limit of the normal range for the blood lactate level, 0.5 mmol/L, is consistent among clinical laboratories, but the upper limit can vary substantially, from 1 to 2.2 mmol/L. Levels at the upper tier of normal values have been associated with increased poor outcomes among seriously ill patients.[194-196] Previously, the definition of lactic acidosis included a blood pH of ≤7.35 or a serum [$HCO3^-$] ≤20 mmol/L.[197] However, the absence of one or both of these features because of coexisting acid-base disorders does not rule out lactic acidosis. For example, coexisting respiratory alkalosis can increase the blood pH into the alkalemic range, whereas the exogenous administration of furosemide or bicarbonate itself can result in both hyperbicarbonatemia and alkalemia. In contrast, coexisting respiratory acidosis can cause severe acidemia. Lactic acidosis during grand mal seizures is associated with normokalemia, because the concurrent entry of lactate and protons into neural cells precludes potassium exit from cells to maintain electroneutrality.[194] An increase in the anion gap can mirror the blood lactate level, but a close relationship might not always be present, because anions other than lactate often contribute to the AG. Thus a normal anion gap does not rule out lactic acidosis. As many as 50% of patients with a serum lactate level of 5 to 10 mmol/L did not have an elevated anion gap.[198] Correction of the anion gap for the effect of serum albumin can improve its sensitivity, but many cases will still escape detection. Therefore the serum anion gap lacks sufficient sensitivity or specificity to serve as a

screening tool for lactic acidosis. Physicochemical indexes, such as SID_{EFF} and SIG, have a better perfomance[199] but always below the direct determination of lactate levels.

Blood lactate concentration, in terms of both the magnitude and the persistence of lactate elevation, has been shown to correlate with mortality in pediatric and adult patients in many situations, including septic and hemorrhagic shock, neonates receiving ventilation, and necrotizing enterocolitis,[119,165,187-192] and it has been used for the titration of inotropes and blood cell transfusions during early goal-directed therapy for severe sepsis and septic shock with a performance not inferior to the mixed venous saturation.[193] Others, however, found no correlation between simultaneously measured $ScvO_2$ and lactate levels in patients with severe systemic inflammatory response syndrome and severe sepsis, but normalization of lactate levels within 48 hours was a predictive factor for survival.[200] Hyperlactatemia may also be present in children following cardiac surgery.[201] Therefore lactate measurement has become a common attribute in point-of-care blood gas analyzers used at bedside in modern ICUs.[202] A new lactate-based categorization of septic shock in adult patients has been proposed: Hyperlactatemia is associated with risk of death independent of vasopressor need resulting in different phenotypes within the classic categories of severe sepsis and septic shock.[203,204]

Lactate represents the end product of anaerobic metabolism (ie, it is a product of pyruvate reduction via the enzyme lactate dehydrogenase and the reduced nicotinamide hypoxanthine dinucleotide/nicotinamide hypoxanthine dinucleotide [NADH/NAD] cofactor system[187,205,206] [see also Chapters 80 and 81]). It derives primarily from skeletal muscle, gut, brain, and circulating erythrocytes, with a production of about 1 mmol/kg/h. The healthy liver uptakes most lactate and recycles it via three primary options: conversion back to glucose (Cori cycle); oxidation back to pyruvate, which subsequently can be oxidized to CO_2 via the Krebs cycle; or transamination into alanine.[205,206] A decrease in oxygen availability at tissue and cellular levels impairs oxidative phosphorylation, which increases the intracellular levels of NADH, the cofactor that facilitates the conversion of pyruvate to lactate. Because of its close relationship with anaerobic metabolism, increased lactate concentration has been largely considered a dead-end waste product of glycolysis due to hypoxia. However, using blood lactate concentration as evidence of tissue hypoperfusion, hypoxia, and hyperactive anaerobic glycolysis is, at best, an oversimplification.[185,196,206]

Evidence now supports the view that sepsis-associated hyperlactatemia is not due only to tissue hypoxia or anaerobic glycolysis and that this response may actually facilitate bioenergetic efficiency through an increase in lactate oxidation. In this sense, the characteristics of lactate production best fit the notion of an adaptive survival response that increases in intensity as disease severity increases.[207-211] Skeletal muscle appears to be a leading source of lactate formation as a result of exaggerated aerobic glycolysis through Na^+/K^+-ATPase stimulation by circulating epinephrine, both endogenous and exogenous.[207-210] Increased lactate as a result of hypoxia or dysoxia may be more the exception than the rule, at least in the hyperdynamic, hypermetabolic phase of sepsis.[199,206-208] Lactate is an important intermediary in numerous metabolic processes, a highly mobile fuel for aerobic metabolism through cell-to-cell shuttles, allowing the coordination of intermediary

metabolism in different tissues and between cells within those tissues.[206] Accordingly, high lactate concentration in septic shock patients can still be interpreted as a marker of the disease's severity, but it should not be taken as an irrefutable proof of oxygen debt or hypoperfusion, needing increases in systemic or regional perfusion or oxygenation to supranormal values.[207,208,211]

During systemic hypoperfusion several tissues are a clear source of lactic acid. For example, underperfused intestine can release lactate but not if mesenteric perfusion is maintained.[107,212] Causes of hyperlactatemia and lactic acidosis are numerous in the critical care setting[186,187,191] (see Table 76.8). Lactate levels may fluctuate in response to exogenous catecholamines, particularly epinephrine, which thereby clearly increases lactate levels through stimulation of glycogenolysis and glycolytic flux with a resultant increase in pyruvate production. This effect does not occur with norepinephrine or dobutamine infusions and is not related to decreased tissue perfusion.[205,213-215] Several studies have shown that the lung is a major source of lactate in severe sepsis/septic shock[214,216] and that decreased lactate clearance by the liver is also an important component of sepsis-associated hyperlactatemia and lactic acidosis.[214,217]

On the other side, the brain is a lactate-consuming organ. Lactate is thought to be an alternative and supplemental fuel for the injured brain and is important for regulating glucose metabolism and cerebral blood flow. Exogenous lactate supplementation may be neuroprotective after experimental acute brain injury. Hypertonic lactate solutions may be a valid therapeutic option for secondary energy dysfunction and elevated intracranial pressure among patients with specific conditions, such as glucose transporter type-1 deficiency syndrome and glycogen-storage disease.[218,219] Therefore instead of just being a biomarker of cellular oxygen debt, persistent lactate elevation often seen in patients with sepsis (and in patients after trauma resuscitation) may be the consequence of more complex physiologic, inflammatory, and metabolic processes.

Although the source and pathophysiologic interpretation of lactic acidosis are matters of discussion, no question exists about the ability of lactate accumulation to produce acidemia. Given its pK_a of 3.9, lactic acid behaves as a strong ion within clinically encountered pH. Therefore the accumulation of lactate (a strong anion) without the addition of an important strong cation such as sodium will be expected to lower the SID, increase $[H^+]$, and decrease the pH. Lactic acidosis would also be expected to be associated with increased adenosine triphosphate (ATP) hydrolysis, another source of hydrogen ions. Because the body can produce and clear lactate rapidly, it functions as one of the most dynamic components of the SID.[205]

Type B lactic acidoses are probably operative in many clinical circumstances where the so-called type A lactic acidoses have traditionally been invocated.[205,207-217] A potentially useful method for distinguishing anaerobically produced lactate from other sources is to measure the whole blood pyruvate concentration. The normal lactate-to-pyruvate ratio is 10 : 1. Because pyruvate is reduced to lactate during anaerobic metabolism, the ratio of lactate to pyruvate increases. If this ratio is higher than 25 : 1, it is considered evidence of anaerobic metabolism.[213] Unfortunately, pyruvate is unstable in solution, and an accurate measurement in the clinical setting is therefore challenging.

In many settings, including septic shock and liver failure, the magnitude of the accumulation of lactate does not always account for the whole of the acid-balance

derangement observed.[85,119,165] In fact, the increase in the AG, SID, and SIG seen in severe sepsis is often substantially greater than the actual lactate concentration. This finding has led to the active search of the so-called unexplained or unmeasured anions (abbreviated [XA⁻] or [UMAs]).[29,107,119] Donnan equilibrium alterations due to sepsis-mediated endothelial damage and a switch from a hepatic anion-uptake state to an anion-release state during endotoxemia have been the main proposals for explaining the fact that as much as 15% to 50% of the increased AG, SID, and SIG are not related to the increased lactate.[29,107,214,216,217] The accumulation of molecules such as succinate, citrate, and formate has also been implicated.[98,99,108,113]

In addition to epinephrine, numerous drugs and toxins encountered in critical care medicine may cause or contribute to increased lactate, with or without acidemia. Likewise, drugs associated with the release of endogenous catecholamines, such as cocaine, can stimulate lactate production.[220] A similar mechanism is advocated in patients with pheochromocytoma.[221] Sodium nitroprusside remains a key vasodilator drug. Because it is metabolized to cyanide and thiocyanate, these toxins may accumulate if excessive drug is administered or cyanide clearance is impaired as occurs in hepatic and renal failure (see also Chapters 126, 127 and 128). In such cases, mitochondrial respiratory chain activity may be inhibited and lactate production increased.[222] Thus nitroprusside toxicity is usually heralded by the rise in lactate levels, with or without a drop in the pH.[205] Similarly, propofol toxicity resulting in lactic acidosis, rhabdomyolysis (including the cardiac muscle), or myocardial, renal, and hepatic failure seems to involve mitochondrial toxicity, which occurs more often with continuous and prolonged infusion, hence the designation *propofol infusion syndrome*.[223,224] As noted previously, in ARDS, lactate levels may be high even in the absence of shock or sepsis.[216] In acute lung injury (ALI)/ARDS, the lung is an important source of lactate.[216,225] This was first evidenced by higher lactate levels in arterial blood than in the mixed blood obtained from patients with ALI/ARDS. A similar phenomenon has been observed in patients receiving mechanical ventilation after cardiopulmonary bypass.[226,227] Potential mechanisms of lactate production by the injured lung may include not only the onset of anaerobic metabolism in hypoxic zones but also direct cytokine effects on pulmonary cells and a stress-induced enhancement of glycolysis and lactate synthesis by both the parenchymal and nonparenchymal cells (eg, endothelial cells and inflammatory cells infiltrating lung tissue such as macrophages and neutrophils).[216,225-227] A similar mechanism is operative in wound tissue, the intestine, and the liver in patients with trauma.[217] Hyperlactatemia occurs in about 80% of cases of acute liver failure.[228,229] Both decreased hepatic clearance of systemically produced lactic acid and increased hepatic production of lactate are involved.[217,228,229] Hypermetabolism associated with lactate accumulation has been found in organs rich in mononuclear phagocytes, especially the liver and spleen. In patients with severe hepatic failure, both the liver and intestine behave as net producers of lactate.[228,229] After transplantation, the grafted liver becomes a net consumer of lactate as evidenced by a negative lactate gradient between hepatic and portal venous blood.

A key concept acknowledges that lactate can be considered a waste product when released from one cell, but it becomes a useful substrate when taken up by another cell. Lactate turnover in vivo in humans is similar to that of glucose, alanine, or glutamine, which means that lactate has one of the highest recycling rates in intermediary metabolism. Accordingly, increased lactate levels can be viewed as an

adaptive response, by which some lactate-producing cells are providing other group of cells with an energy substrate via the so-called lactate shuttle.[206,230]

Lactic acidosis in status asthmaticus seems to be multifactorial and includes contributions from lactate production by overwhelmed respiratory muscles, tissue hypoxia, a hyperadrenergic state, and the metabolic effect of pharmacologic β_2 agonists.[231-236] Non-lactic, non-AG acidosis has been described in adults presenting with status asthmaticus and seems to be related to hyperchloremia associated with exacerbated chronic hypocapnia.[237] In multiple trauma, lactic acidosis can occur as an effect of polytrauma and hemorrhagic shock and as a manifestation of severe traumatic brain injury, and it is a risk factor for adverse outcomes.[238] Salicylate intoxication is a special situation in which lactic acidosis may play an important role (see also Chapters 127 and 128). Although salicylate toxicity occurs less frequently now than in the past because of the increased use of alternative antipyretics in young children, it must still be considered in certain therapeutic situations (eg, rheumatic diseases), as well as in cases of intentional or iatrogenic overdose. It remains as a potential pediatric health hazard, rising concern as children are more fragile to salicylate poisoning because of their reduced ability of buffer the acid stress.[239] Salicylates directly or indirectly affect most organ systems in the body by uncoupling oxidative phosphorylation, inhibiting Krebs cycle enzymes, and inhibiting amino acid synthesis. These derangements can result in variable acid-base patterns: respiratory alkalosis, mixed respiratory alkalosis plus metabolic acidosis, or (less commonly) simple metabolic acidosis.[240] A *paradoxical aciduria* may occur despite respiratory alkalosis and aggravate the clinical manifestations because a higher percentage of salicylate in acidic urine remains in the unionized form, which is reabsorbed from the glomerular filtrate. Metabolic acidosis is mainly due to lactic acid, but ketoacids and other metabolic acids also participate. Chronic salicylate poisoning has been described, in which the patients usually have metabolic acidosis and a pseudosepsis syndrome, similar to some inborn errors of metabolism, with high rate of permanent organ dysfunctions and mortality.[241]

Elevation of blood lactate up to the 5 mmol/L level may be seen in about 25% of human immunodeficiency virus (HIV)-positive patients who receive nucleoside reverse transcriptase inhibitors (mainly stavudine). Most patients remain asymptomatic, but a small proportion may present with dyspnea and abdominal pain, as manifestations of lactic acidosis, 3 to 4 months after starting the treatment. If the drug is discontinued and fluids are replaced, the process is reversible. The mechanism appears to involve uncoupled oxidative phosphorylation due to an inhibition of DNA polymerase-gamma.[242]

As a result of the worldwide problem of obesity, increasing numbers of school-age children receive some treatment for the peripheral resistance to insulin. Thus metformin, formerly limited to adult patients, is now being used with increasing frequency in children. The incidence of metformin-associated lactic acidosis is low, but it has a high mortality rate. Obese children and adolescents who receive metformin in the setting of intercurrent illnesses that may predispose to accumulation of the drug (eg, renal function impairment) are at risk of developing metformin-associated lactic acidosis.[243] It also may occur as a consequence of accidental ingestion or a suicidal attempt. Survival depends on the nadir pH and the maximum concentration of lactate and metformin. The mechanism involves uncoupling of the oxidative-phosphorylation with acceleration of the glycolytic flux,

which increases lactate production. From 1960 to 2000 the overall mortality rate for metformin-associated lactic acidosis was around 50%, but it has since fallen to around 25%.[244]

A curious form of lactic acidosis is the so-called D-lactic acidosis. Lactic acid produced by mammals is a levo-isomer. Dextroisomer (D)-lactate derived from bacterial fermentation in the bowel lumen may reach systemic circulation and lead to metabolic acidemia, especially if liver function (and thus lactate clearance) is suboptimal.[245] D-lactic acidosis must be considered in patients with a history of intestinal disease who have neurologic findings such as confusion and ataxia, and high AG metabolic acidosis, with normal L-lactate levels. Symptoms worsen after high-carbohydrate meals or tube hyperalimentation. In patients with short bowel syndrome, there may be not only an overgrowth of bacteria but also an accumulation of carbohydrates in the colon. Treatment focuses on decreasing gut bacteria overgrowth with antibiotics and the avoidance of high-carbohydrate or lactose feeding. Some studies have advocated the use of probiotics for treating and preventing this problem,[246] but the reports are conflicting.[247,248]

The use of linezolid has increased with the emergence of multidrug-resistant bacteria, including *Staphylococcus aureus* and *Mycobacterium tuberculosis*. Serum lactic acidosis has been reported as a serious side effect of linezolid. Prolonged administration of linezolid (>6 weeks) is one of the risk factors for metabolic acidosis. Studies confirm that this adverse drug event may be predicted with genetic testing.[249,250]

Ketoacidosis

Ketones are formed by beta-oxidation of fatty acids, a process that increases substantially in insulin-deficient states. In the pediatric intensive care setting, this is most often seen in patients with DKA with overproduction and underutilization of acetone, β-hydroxybutyric (βOH-B), and acetoacetic acids (ketone bodies), which accumulate in plasma (see also Chapter 86). Ketoacidosis is also seen in various inborn errors of amino acid and organic acid metabolism, and a mixed ketoacidosis and lactic acidosis are seen with glycogen storage disease type I (glucose-6-phosphate deficiency) (see also Chapter 82). The urinary dipstick for ketones uses a nitroprusside reagent, hence it detects acetoacetate but not βOH-B. If a patient with DKA develops shock, βOH-B may be produced in ratios up to 3 : 1. Hence the urinary dipstick will mistakenly appear to have few ketones, and their concentration may paradoxically rise as perfusion improves and the patient gets better.[251,252] Capillary blood determination of βOH-B is a better alternative for DKA treatment guidance.[252,253] As the renal threshold for the ketone bodies is low, they are readily filtered, with no reabsorption mechanism, and the kidneys can eliminate a significant number of ketones. This loss can shift the AG, which may appear less than expected, because of the anions eliminated though the urine, with renal retention of chloride and bicarbonate. The picture can be even more complicated if hypocapnia from hyperventilation is present. Therefore AG (even corrected AG) may not be instructive; SIG may be more useful in such complicated scenarios.[111] Alcoholic ketoacidosis (AKA) is most frequent in patients with chronic ethanol intake and liver disease, and it usually occurs after a period of heavy drinking in association with reduced food intake. AKA is quickly responsive to fluid administration, with faster resolution when dextrose and saline are infused

together.[254]

Toxic Compounds That Directly Provoke Acidosis

Alcohol intoxications, including methanol, ethylene glycol, diethylene glycol, and propylene glycol, may present with a high anion gap metabolic acidosis, a decrease in serum bicarbonate, and an increased serum osmolality and osmolal gap (see also Chapter 127). The acidosis and cellular dysfunction are direct effects of the metabolites of these substances, whereas the parent compounds are associated with an increase in serum osmolality. These are rather infrequent problems in pediatric cases, but adolescents who ingest alcohol or illicit drugs (including inhalants) or have suicidal risks are potential victims.[254] The clinical presentation may range from mild subclinical poisoning to an unexpected and rather sudden onset of high anion gap acidosis, renal failure, and encephalopathy, with an increased risk for mortality and neurologic sequelae.[255] The intoxication is best treated with supportive critical care including alkalinization and early continuous hemofiltration or hemodiafiltration. A competitive inhibitor of alcohol dehydrogenase (4-methylpyrazole [or fomepizole]) is available for use in ethylene glycol and methanol poisoning (possibly also useful in diethylene glycol and propylene glycol intoxications), but extracorporeal removal should always be employed for serious poisoning. For methanol and ethylene glycol, ethanol infusion is an alternative competitive inhibitor of the alcohol-dehydrogenase ezyme.[254,256]

Other Forms of Metabolic Acidosis Associated With an Increased Anion Gap

Late metabolic acidosis of prematurity[257] occurs more frequently in the premature infant when compared with the term infant (20% versus 5%). Limited capacity of less well developed renal tubules to excrete H^+ and Cl^- and to concentrate is a fairly common situation during the first month of life. Although this level of renal tubular development is adequate for the breast-fed infant, if the protein intake or solute load is excessive, the renal capacity may be exceeded and a metabolic acidosis may develop, particularly during periods of stress. In the setting of renal disease generally, the clinician must anticipate the occurrence of metabolic derangements. When chronic renal insufficiency develops, hyperchloremic metabolic acidosis, a nonanion gap acidosis, may initially occur because of impaired ammonium (NH_4^+) generation and excretion. When the glomerular filtration rate (GFR) falls below 20 mL/min, the kidneys are incapable of excreting fixed acids. The resulting accumulation of sulfates among other acids may increase the AG. These acidoses are usually mild, producing an excess AG of approximately 10 mEq/L. A mixed metabolic acidosis (high and normal AG mechanisms) is not uncommon in this setting.[63,251] If the patient has sepsis or another condition associated with hypermetabolism, however, the rate of acid generation increases and the acidosis may become severe. The SID decreases, and because of the lack of renal compensation, some intervention is required. Patients who do not yet require dialysis and those who are between their dialytic sessions are often given sodium bicarbonate (provided there is no hypernatremia) or sodium potassium citrate.[258] When bicarbonate is contraindicated, dialytic therapy is indicated.

Hyperchloremic Acidoses: The Nonanion Gap Metabolic Acidoses

In the classical view, hyperchloremia was considered an epiphenomenon of a drop of the concentration of bicarbonate, due to its *abnormal loss* through urine or stools (see Table 76.4). The rise in chloride concentration is responsible for maintaining a "normal" anion gap, in spite of the drop in bicarbonate levels (ie, a *nonanion gap* acidosis is produced). When bicarbonate is *consumed* to buffer an acid load, hyperchloremia is not produced, because there are other anions, deriving from the acid load, that will preserve electroneutrality as bicarbonate falls. In this case, the anion gap increases because of the presence of these new (and unmeasured) anions.[63,124] However, physiologic thought is moving from kidneys that directly sense and regulate $[H^+]$ to kidneys that react to Cl^- balance and therefore control directly the independent variable SID in the acid-base regulation. This change is supported by identification of several ion transporters in the renal tubules.[95-97,144,162,259-262] Thus hyperchloremic acidoses occur either as a result of an increase in chloride concentration relative to strong cations (especially sodium) or because of the loss of cations with a retention of chloride (see Table 76.6). When the pH drops, the normal response by the kidney is to increase chloride excretion as ammonium chloride (NH_4Cl) in order to increase the SID and raise back the pH. Thus the role of the formation of ammonium (NH_4^+) and its eventual tubular excretion is not so much the elimination of H^+ but rather Cl^- excretion without the loss of sodium or potassium. Failure of this mechanism identifies the kidney as the problem, as in renal tubular acidosis (RTA).[63,199,251] There are four main causes of nonanion gap acidoses: (1) exogenous chloride loads (saline boluses, parenteral nutrition, etc.); (2) loss of cations from the lower gastrointestinal tract without proportional losses of chloride, as in secretory diarrhea, but also in conditions in which alkaline loss of small bowel, biliary, or pancreatic secretions are present (such as drainage from ostomies, tubes, or fistulas); (3) renal tubular acidoses and drug-mediated tubulopathies; and (4) urinary reconstruction using bowel segments.

Exogenous Chloride Load

In the critical care unit there are often mandatory therapeutic interventions associated with hyperchloremic metabolic acidosis. The more common interventions are the rapid infusion of isotonic saline (0.9% NaCl) and the infusion of parenteral nutrition. As stated before, the classical explanation for acidosis following saline administration was the so-called bicarbonate dilution. This mechanism probably can play a role in certain conditions.[143,163] Healthy, metabolically stable individuals have a plasma SID of around 40 mEq/L, and it is around 30 mEq/L in critically ill patients. But the SID of normal saline is *zero* mEq/L, because sodium and chloride are both strong ions. Therefore IV administration of 0.9% NaCl necessarily will decrease plasma SID, creating a strong ion acidosis, as long as the infusion does not cause a change in PCO_2 or albumin or phosphate concentrations. Hyperchloremic acidosis should be expected whenever large volumes of normal saline are rapidly administered, such as in fluid boluses for treating shock or during surgical procedures.[148,152,156,159] Even the acid-base status of disorders in which one or more unmeasured anions will be participating (septic shock [lactate], DKA [ketones]) is

influenced by the chloride infused with resuscitation fluids.[150,152,155,157,263] In one study of 81 children with meningococcal sepsis, metabolic acidosis was common and prolonged (persisted for 48 hours), but the pathophysiology changed from one of unmeasured anions at admission to predominant hyperchloremia by 8 to 12 hours.[152] There is no doubt about the relationship between normal saline resuscitation and the development of hyperchloremia and acidosis (not necessarily acidemia).[152,163,262,264] However, it is not clear if this hyperchloremic acidosis is really detrimental.[115,118,157-160,264] Actually, in a group of 97 children evaluated in their postoperative period following open cardiac surgery, the occurrence of hyperchloremia was associated with a reduced requirement for epinephrine therapy, so the authors suggested that hyperchloremic metabolic acidosis is a benign finding.[148] A review concluded that there is an accumulating trend in scientific evidence showing that both hyperchloremia and hyperchloremic acidoses have subtle but potentially significant adverse physiologic and clinical effects.[158] It is unclear whether the acidosis or the high chloride levels should be of concern. The effects of hyperchloremia and hyperchloremic acidosis may not influence outcome for most patients. Given that hyperchloremic acidosis is often iatrogenic and it is associated with proved morbidity (increased ICU length of stay, delayed DKA recovery, increased incidence of postoperative nausea/emesis),[263] it has been suggested that normal saline should be avoided whenever possible.[158,265]

Several groups have assessed the use of the so-called balanced fluids—that is, fluids with SID nearer to the SID of human plasma.[156,259,265,266] However, this suggested change of practice is still inconclusive. At least one prospective study in adults suggested that the amount of fluids given, rather than the types of fluid, had the stronger effect on the changes in base excess.[267] It is probably wise to view normal saline as a potential hazard, especially in patients with previously known renal or liver dysfunction, those with shock, and surgical patients needing high amounts of intraoperative saline for resuscitation.[268] It has been suggested that intraoperative serial chloride determinations may unmask or exclude hyperchloremia as a cause of acidosis, undetectable through SBE alone.[159]

Parenteral nutrition formulas contain weak anions, such as acetate, in addition to chloride, and thus they are buffered. However, with an insufficient number of weak anions, plasma $[Cl^-]$ will increase, SID will decrease, and acidosis may result.[97]

Postpyloric Gastrointestinal Fluid Losses

The gastrointestinal (GI) tract, liver, and pancreas can be conceptualized as a giant ion exchanger organ. Throughout all the sequential segments of the GI tract, a distinct group of ion transporters and channels interact with one another to determine the electrolyte content, pH, and volume of the fluid in the gut lumen. The main transport system is driven primarily by Na^+/K^+-ATPase across the basolateral membrane of the epithelial cells, with the participation of several key apical membrane electrolyte transporters, including Cl^-/HCO_3^- and Na^+/H^+ ion exchangers and the so-called *cystic fibrosis transmembrane conductance regulator, or CFTR Cl^- channel.* Large numbers of cations and anions traverse the specialized epithelia of the gut every day. This transport is adjusted for achieving an efficient absorption of dietary components, rather than for acid-base homeostasis. Under normal conditions, only a small net amount of alkali (30-40 mmol per day) is lost in stool, so

the kidney and lungs have no problem compensating for pH. However, the disruption of normal gut function can provoke disorders that vary from severe acidosis (most of postpyloric losses) to severe alkalosis (prepyloric losses, congenital chloridorrhea), depending on the segment of the GI tract affected and the nature of the losses that ensue.[269] For acid-base and electrolytes abnormalities to occur in diarrheal diseases, the volume of fluid lost must be large enough to exceed the kidney's ability to adjust excretion to maintain acid-base balance. With large losses, any form of diarrhea may lead to a significant fall in extracellular fluid volume, reducing the GFR and limiting the ability of the kidneys to compensate for the problem. Secretory diarrheas (cholera, enteropathic *E. coli,* rotavirus, and other infectious diarrheas) most commonly produce this clinical scenario, with the typical presentation of hypovolemia, hypotension, acute renal failure, hyperchloremic metabolic acidosis (lost stools are usually rich in sodium, potassium, and bicarbonate, so SID decreases), and hypokalemia. If the hypovolemia and hypotension are not corrected, lactic acidosis superimposes, as a result of tissue hypoperfusion. AG_{CORR}, initially normal, may increase gradually, but more frequently it will remain normal in spite of lactacidemia, hence the value of measuring lactate levels. The mechanism of the acidosis is well defined for cholera diarrhea but is less defined for other pathogens. *Vibrio cholera* produces a toxin that increases cAMP levels in intestinal crypt cells, producing a sustained activation of the apical membrane CFTR Cl^- channel and thereby leading to excessive Cl^- secretion into the ileum and colon. This increased chloride secretion in turn stimulates the apical Cl^-/HCO_3^- exchanger, increasing the bicarbonate concentration in stools, which results in increased paracellular Na^+ and water entry, resulting in high-volume losses that contain a large amount of HCO_3^-, as well as Na^+, Cl^-, and K^+. The lost fluid and electrolytes can be replaced with oral solutions (100 mL/kg body weight of a solution with 60 to 90 mEq/L of sodium).[270] In cases of excessive losses or emesis, vigorous intravenous volume repletion must be implemented. Diarrhea due to laxative abuse can be seen in bulimic or anorexia nervosa adolescents, but it is usually not associated with acid-base derangements; however, if excessive diarrheal losses are induced, metabolic acidosis can occur, as with any severe diarrhea.[269]

Both biliary and pancreatic secretions have alkaline pH. When pancreatic or biliary drainages are required after surgery, usually the volume is low, so despite the loss of a $NaHCO_3$-rich fluid, significant metabolic acidosis does not occur. In the rare occasions in which such drainage is excessive (>30 mL/kg/day), metabolic acidosis will develop and be maintained by concomitant volume depletion. Replenishment with sodium solutions will restore SID. Bicarbonate administration is equally effective.[269] Patients with well-functioning ileostomies usually adapt to the extra fluid obligatory loss through subtle changes in salt and water intake, as well as changes in urine volume and electrolyte and acid excretion. If the ileostomy drainage abruptly increases, resultant salt and water losses can easily lead to clinically significant volume depletion. In this setting, the development of metabolic acidosis is common, because $[HCO_3^-]$ in ileostomy fluid is usually higher than in plasma, causing disproportionate sodium and alkali loss. Hyperkalemia usually presents with this metabolic acidosis, indicating that K^+ is not secreted into the ileum. In addition, renal K^+ excretion is decreased with volume depletion.

Renal Tubular Acidoses and Drug-Mediated Tubulopathies

RTA comprises a group of disorders characterized by a low capacity for net acid excretion (NAE) and persistent hyperchloremic, as well as metabolic, acidosis with normal anion gap and normal or minimally affected filtration rate (GFR). On the basis of functional studies, RTA has traditionally been separated into three main categories: (1) proximal RTA, or type 2; (2) distal RTA, or type 1; and (3) hyperkalemic RTA, or type 4. Sometimes a fourth kind is added: combined proximal and distal RTA (mixed RTA), or type 3.[271] Type 4 RTA is of special interest in the critical care setting, as the hyperkalemia may be triggered by some drugs used in intensive care units, such as converting enzyme inhibitors, heparin, trimethoprim, α-adrenergic agonists, β-adrenergic antagonists, digoxin, and others. Classical RTA teaching states that metabolic acidosis arises from a lack of urine excretion of protons (hydrogen ions) or an excessive loss of bicarbonate due to a variety of tubular disorders.[271] Molecular studies have identified genetic or acquired defects in transporters of protons and bicarbonate in most varieties of RTA.[271,272] This classical physiologic view has been challenged by the physicochemical acid-base interpretation; it is supported by the fact that these transporters are also involved in Cl^- and Na^+ transport and that at least certain cases of RTA are clearly associated with primary defects in electrolyte transporters alone. In an illustrative study, 12 children with alkali-treated distal RTA were compared with healthy controls. Both groups received a load of hypotonic saline (0.45%), but only the RTA patients exhibited subsequent hyperchloremia and metabolic acidosis, associated with the high total and distal fractional absorption of chloride. However, urinary excretion of bicarbonate did not correlate with changes in either blood pH or plasma bicarbonate concentration. Thus renal tubular avidity for chloride absorption was primarily increased in RTA.[162,261,273] These tubular transport mechanisms determine the excretion of strong ions, Na^+, K^+, and Cl^- and hence the balance of the concentration of SID, both in the extracellular compartment dominated by Na^+ and Cl^- and in the intracellular compartment dominated by K^+. SID determines pH, and by way of sensor and effector mechanisms it must provide feedback to tubular activity. Thus acid-base homeostasis is directly regulated by electrolyte transport in renal tubules, and hydrogen ions and bicarbonate movement represent the balancing requirement imposed by physical chemistry.[104,162,261,273] This reasoning supports the notion that the role of NH_4^+ is more related to the elimination of Cl^- without losing Na^+ or K^+ rather than to the titration of urinary H^+.[104,261,273] According to the physicochemical approach, the underlying defect in all RTA types is an inability to excrete chloride in proportion to sodium, although the transporter involved dictates the specific type of RTA.[162,261,273] In the critical care setting, the presence of RTA may complicate management of the resuscitation fluids including acid-base balance. Previously unknown RTA must be suspected whenever a patient's clinical condition does not improve as expected with the proper therapeutic interventions. Treatment largely depends on whether there are losses of sodium that can be replaced with $NaHCO_3$ or whether the kidney will require mineralocorticoid replacement. It is worth mentioning that urinary AG (uGAP = $[uNa^+ + uK^+] - [uCl^-]$),[195] more recently termed the *urine strong ion difference*,[97,199] is useful in the diagnostic workup of the patient with hyperchloremic acidosis. If it is negative ($uCl^- > uNa^+ + uK^+$), it suggests GI bicarbonate loss, acute infusion of a high volume of saline isotonic fluid (NaCl 0.9%),

or a proximal RTA. On the other hand, if the uGAP is positive ($uCl^- < uNa^+ + uK^+$), it suggests the presence of a distal renal defect.

Also of importance to the intensivist is iatrogenic renal tubular acidosis caused by the nephrotoxicity of amphotericin B, aminoglycosides, and other drugs. Kidney alterations due to amphotericin B include decreased GFR, distal tubulopathy with urinary loss of potassium and magnesium, RTA, loss of urine concentration ability, and sometimes the Fanconi syndrome. Nephrotoxicity is related to treatment duration, dosing schedule, cumulative dosage, concurrent diuretics treatment, and the administration of other nephrotoxic drugs (aminoglycosides, cyclosporin A, tacrolimus, cisplatin, ifosfamide). Each dose increment of 0.1 mg/kg/day has been found to be associated with a 1.8-fold increase in the risk of nephrotoxicity.[274] Mechanisms of amphotericin nephrotoxicity include the deoxycholate vehicle for amphotericin B, reduction in renal blood flow and GFR, increased salt concentration at the macula densa, interaction of amphotericin B with ergosterol in the cell membrane, and apoptosis in proximal tubular and medullary interstitial cells. Salt loading, with a daily sodium intake >4 mEq/kg/day, is the only measure proved by a controlled prospective study to ameliorate amphotericin B nephrotoxicity in humans, including extremely low-birth-weight infants.[275] Proper hydration must be assured prior to administration of the drug. Lipid formulations of amphotericin B (liposomal, lipid complex, colloidal dispersion) are indicated in children receiving other nephrotoxic drugs, those with already reduced GFR, or those with previously documented amphotericin adverse events. Total dose ≥35 mg, chronic renal disease, concomitant use of cyclosporine or amikacin, and male gender have been identified in adults as risk factors. Patients with more than two risk factors showed an incidence of moderate-to-severe nephrotoxicity of 29%.[276]

Trimethoprim-sulfamethoxazole is another antimicrobial that has been related to RTA and hyperchloremic metabolic acidosis.[277] Topiramate, one of the new anticonvulsant drugs, has been reported to cause hyperchloremic metabolic acidosis in children and adults. Topiramate inhibits the enzyme carbonic anhydrase, and thus a type 3 or mixed RTA is produced.[278] Another rare cause of normal AG metabolic acidosis that may be seen in the ICU is acetazolamide, a carbonic anhydrase inhibitor used occasionally to decrease cerebral spinal fluid production in conditions of hydrocephalus and to stimulate renal bicarbonate wasting.[279] This drug decreases hydrolysis of H_2CO_3 to CO_2 and H_2O, resulting in a decrease of renal HCO_3^- reabsorption. Rarely acetazolamide can produce a severe lactic acidosis with elevated anion gap, increased lactate-to-pyruvate ratio, ketosis with a low β-hydroxybutyrate-to-acetoacetate ratio, and a urinary organic acid profile typical of pyruvate carboxylase deficiency.[280] This acquired enzymatic injury stems from the inhibition of mitochondrial carbonic anhydrase type V.

Urinary Reconstruction Using Bowel Segments

Children with irreversible lower urinary tract dysfunction due to developmental abnormalities involving the genitourinary (GU) system, neurogenic and myogenic bladder, may require urologic surgical procedures for their management, including urinary diversion and enterocystoplasty. Various techniques and bowel segments can be used depending on the clinical situation. The GI tract is a relatively poor substitute for urothelium, and its semipermeability allows nonphysiologic fluid and

electrolyte absorption leading to metabolic abnormalities.[281] The significance of these problems is related to the portion of the GI tract used and the length of time the urineis exposed to the bowel surface. In addition, if the loss of some portions of the GI tract results in chronic diarrhea, there may be further metabolic consequences. Jejunal substitution is typically associated with hyponatremic/hypochloremic/hyperkalemic acidosis, clinically manifested by nausea, vomiting, anorexia, and muscular weakness. Hyperchloremic/hypokalemic metabolic acidosis can also occur when the ileum or colon is used for the GU reconstruction. In less severe cases, a chronic metabolic acidosis may go undetected, resulting in growth retardation. In one series, 41% of children with bowel segment urinary reconstruction required chronic prophylactic alkaline substitution.[282,281] Thus although acute decompensations may require intravenous correction of the acidosis with bicarbonate or fluid administration, most cases will maintain electrolyte balance with lifelong alkalinization with enteral bicarbonate, sodium citrate, or citric acid solutions.

Treating Metabolic Acidosis

Treatment of metabolic acidosis should focus on the underlying cause. Certain acidoses have specific therapies, such as insulin and fluids for the patient with DKA, $NaHCO_3$ and citrate for patients with the classic distal RTA, and fomepizole for methanol or ethylene glycol intoxication. The following discussion focuses on lactic acidosis, unless otherwise mentioned.

Sodium Bicarbonate

$NaHCO_3$ administration has long been the standard therapy for metabolic acidosis including lactic acidosis.[63,168,251] There is consensus regarding the advantages of alkali and sodium bicarbonate therapy of normal anion gap acidosis. However, in the presence of high anion gap acidosis, especially lactic acidosis (in shock and cardiopulmonary resuscitation) and diabetic acidosis, there is negative safety and efficacy evidence for use of sodium bicarbonate. Justification for the persistent use of bicarbonate comes from a variety of sources, many based more in philosophy than in science.[63,168,172,251,283,284] In agreement with Eqs. 20 and 21, administration of $NaHCO_3$ increases the SID (which tends to raise the pH) because sodium is a strong cation and bicarbonate is a weak anion, but in agreement with Eq. 11, bicarbonate is an anion that rapidly converts to carbonic acid and then to CO_2, which tends to lower the pH.[172,285,286] Therefore $NaHCO_3$ may increase arterial pH if, and only if, alveolar ventilation is adequate.[168,172,283-290] *Paradoxical intracellular acidosis* following bicarbonate administration does not always occur, nor is it always detrimental to the cell.[128,172,286,287] The ultimate effect of $NaHCO_3$ on intracellular pH depends on changes in PCO_2 in the medium bathing the cells, which is influenced by the extracellular nonbicarbonate buffering capacity.[286] In addition, bicarbonate administration may promote metabolic reactions that may themselves alter not only PCO_2 but also the total concentration of weak acids and the SID. It has been documented that bicarbonate can increase the production of lactic acid in both animals and humans.[172] Mechanisms to explain this reaction remain speculative but include a shift in the

oxyhemoglobin-saturation relationship, enhanced anaerobic glycolysis probably mediated by the pH-sensitive enzyme phosphofructokinase, and changes in hepatic blood flow or lactate uptake.[172,214] Clinical experience has confirmed that arterial pH can be raised and even normalized with $NaHCO_3$.[63,168,172,251] However, even when $NaHCO_3$ added to central venous blood reliably elevates the arterial pH, its effect can be erratic at tissue and cellular levels. For example, in the cerebrospinal fluid and intracellular spaces, pH may drop further, without concordance with an already alkalemic arterial blood sample. In fact, in most animal models and in most organs studied to date, including the brain in healthy human volunteers, intracellular pH decreases with bicarbonate administration.[172,185,286,287] Results of human studies examining the impact of bicarbonate administration during cardiopulmonary resuscitation have uniformly shown no benefit in terms of survival and hemodynamic recovery.[168,172,185,285] Accordingly the American Heart Association no longer recommends routine administration of sodium bicarbonate during cardiopulmonary resuscitation. Its use may be considered only after effective ventilation, chest compressions, and epinephrine administration have occurred and for cases in which bicarbonate is a specific therapeutic intervention (eg, hyperkalemia, hypermagnesemia, tricyclic antidepressant poisoning, cocaine cardiac effects, and sodium channel blocker poisoning).[291] Similarly there is also no evidence of benefit with sodium bicarbonate infusion during resuscitation of neonates.[292,293] Reported hemodynamic responses to bicarbonate administration in patients treated with inotropic/vasoactive drug infusions may simply be due to preload augmentation rather than enhanced catecholamine responsiveness.[168,172]

Data suggesting increased mortality with bicarbonate administration continue to appear.[294-296] Even with severe acidosis (pH <7) the role of bicarbonate is unclear, as no reliable argument exists to prove that this acidosis is harmful under these conditions in humans.[211,289,290] However, the 2007 update of the Clinical Practice Parameters for hemodynamic support of pediatric and neonatal septic shock from the American College of Critical Care Medicine[297] stated that sepsis-induced acidosis and hypoxia can increase pulmonary vascular resistance. Although inhaled nitric oxide is the treatment of choice, the committee concluded that metabolic alkalinization remains an important initial resuscitative strategy during shock, as pulmonary hypertension in the setting of septic shock can reverse when acidosis is corrected. A small, adult observational study applied a quantitative acid-base analysis approach to clarify the components of sepsis-associated metabolic acidosis.[298] The study subjects presented with a complex pattern of metabolic acidosis, caused predominantly by hyperchloremic acidosis. Acidosis resolution among survivors was attributable to a decrease in strong ion gap and lactate levels. This study suggested that a subset of sepsis/septic shock patients (those with hyperchloremic acidosis identified by SIG and $AG_{CORRLACT}$) may indeed benefit from sodium bicarbonate administration.

Adverse side effects of $NaHCO_3$ relate to fluid and sodium loads that can cause hypervolemia, hyperosmolarity, and hypernatremia.[283] Given as a rapid intravenous (IV) bolus, $NaHCO_3$ can cause a transient decrease in arterial blood pressure and a transient rise in intracranial pressure, probably related to its hypertonicity.[172] Intravenous bicarbonate administration can cause sudden shifts of several cations through cell membrane–mediated mechanisms. Although advantageous in treating

hyperkalemia,[291] this strategy can be dangerous because bicarbonate lowers ionized calcium. Overshoot alkalosis can result from overly aggressive bicarbonate correction.[288-290] If used, the amount of bicarbonate administered should raise the pH up to 7.2.[290]

Salicylate intoxication represents a special setting. Because the risk of death and the severity of neurologic manifestations depend on the concentration of salicylates in the central nervous system, therapy is directed at limiting further drug absorption by administering activated charcoal in the emergency department and promoting the exit of the drug from the cerebral tissue by increasing the alkalinity of the blood, which will also raise urine pH and therefore inhibit salicylate reabsorption by ion trapping (see also Chapters 127 and 128). The target pH of the urine is 7 to 7.5. Hemodialysis is utilized for severe salicylate intoxication, especially that involving renal dysfunction.

If a decision is made to administer $NaHCO_3$, some time-honored clinical clues are valuable. $NaHCO_3$ dose is best estimated using either the SBE or the bicarbonate level derived from PCO_2 measured by the blood gas analyzer:

$$\text{Total body base deficit} = \text{SBE} \times \text{body weight (kg)} \times 0.3 \qquad \textbf{(Eq. 26)}$$

$$\begin{aligned}\text{HCO}_3^- \text{ deficit (mEq)} &= 0.3 \times \text{body weight (kg)} \\ &\quad \times [\text{HCO}_3^- \text{ expected} - \text{HCO}_3^- \text{ observed}]\end{aligned} \qquad \textbf{(Eq. 27)}$$

Distribution volume of bicarbonate is 30% of the lean body weight. The theoretic distribution volume of $NaHCO_3$ equals the extracellular fluid volume, which grossly represents 60% of the body weight (70% in young infants), and therefore it can be argued that the correct arithmetic factor should be 0.6 rather than 0.3. Experience has shown, however, that as a starting point, bicarbonate or SBE correction with 0.3 (“half correction”) will suffice in most cases and will avoid unnecessary risks from an excessive load of solutes and fluid as well as the overshoot alkalemia.

Alternative Alkalinizing Agents

Concern about the CO_2-producing effect of bicarbonate led to the development of carbicarb, which consists of equimolar concentrations of sodium bicarbonate ($NaHCO_3$) and sodium carbonate (Na_2CO_3).[168,222,299,300] Carbicarb raises the SID and thus increases the pH far more than bicarbonate, with much less rise in PCO_2. Risks of hypervolemia and hypertonicity are similar to those of bicarbonate. Although carbicarb more consistently increases intracellular pH, studies of its effects on hemodynamics have yielded conflicting results.[222] Carbicarb is not currently available for clinical use, pending further clinical research.

THAM (tris[hydroxymethyl]aminomethane), also known as tromethamine and tris-buffer, is an amino alcohol that behaves as a weak base (pK_a 7.8). It exists in neutral form at physiologic pH. Protonated THAM is excreted by the kidneys.[301] It crosses lipid membranes and penetrates cells easily. Therefore it has the potential to

raise both intracellular and central nervous system pH. In addition, THAM's buffering action occurs without producing CO_2 and thus is not dependent on pulmonary function.[302] Even though THAM has been commercially available for several decades, there are few studies establishing its clinical efficacy. In animal models, THAM incompletely buffered metabolic acidosis but significantly improved contractility and relaxation in an isolated rabbit heart model.[168] A small adult ICU study showed that THAM had an equivalent but shorter-lasting alkalinizing effect in comparison to that of bicarbonate, but it produced no decrease in potassium and did not increase sodium.[303] A paucity of clinical information and the report of several serious side effects, including hyperkalemia, hypoglycemia, local extravasation injury, and hepatic necrosis in neonates, have limited its widespread clinical use.

Of particular relevance for lactic acidosis is dichloroacetate (DCA), a simple compound that reduces plasma lactic acid concentration. DCA is not a buffer but a stimulator of pyruvate dehydrogenase, the enzyme that catalyzes the oxidation of pyruvate to acetylcoenzyme A (CoA), facilitating its entry to the Krebs cycle and thus decreasing lactate production and promoting the clearance of accumulated lactate.[168,304] In addition, DCA promotes myocardial glucose utilization and contractility. Initial data from both children and adults were promising,[286] but a large controlled clinical trial in adults with severe lactic acidosis showed that DCA treatment resulted in statistically significant but clinically unimportant changes in arterial blood lactate concentrations and pH. It also failed to alter hemodynamics or survival. Renewed interest in DCA has arisen from its potential applications for attenuating lactic acidosis in certain congenital errors of metabolism[305] and lactic acidosis due to severe malaria in children.[306]

Dialysis Management of Metabolic Acidosis

Dialytic procedures may be indicated in some cases of metabolic acidosis that are refractory to bicarbonate or in cases in which there are serious limitations in the amount of fluid or sodium load that can be administered to the patient, a common situation in the pediatric critical care unit (see also Chapter 78). Uncompensated metabolic acidosis (pH <7.1) remains one of the acknowledged criteria for the initiation of renal replacement therapy in the pediatric ICU.[284] Peritoneal dialysis is often not the best choice, particularly in lactic acidosis associated with hypoperfusion. In this setting the hypoperfused peritoneal membranes may not be efficient for supporting enough peritoneal flux, and the increase in intraabdominal pressure may contribute to a further drop of cardiac output. If peritoneal dialysis is chosen, bicarbonate-buffered peritoneal dialysis solution provides some advantages over the conventional lactate-buffered peritoneal dialysis solution in terms of both pH control and mesothelial cell preservation. Most critically ill patients lack the hemodynamic stability to tolerate intermittent hemodialysis. Hemofiltration and hemodiafiltration are better options. Acute renal replacement therapy may be needed for critically ill patients with metabolic acidosis that is multifactorial in origin. Once continuous hemofiltration is started, it becomes the dominant force in controlling metabolic acid-base status and profound changes are rapidly achieved. The result is the progressive resolution of acidemia and acidosis, with lowering concentrations of phosphate and unmeasured anions. Hemofiltration techniques replace plasma water, which is low in bicarbonate concentration and has decreased

SID, with a solution that contains an above-normal sodium bicarbonate (or lactate or acetate) concentration. Such weak anions free their sodium (which increases SID), buffer hydrogen ions, and then are transformed into CO_2 (lactate and acetate must convert first to bicarbonate in the liver), which is removed by ventilation. This exchange contributes to the correction of acidosis, along with the increase in SID through the sodium contribution. If these oxidizable anions are not fully extracted and metabolized by the liver, they accumulate in plasma and their ability to correct acidosis is lost, as they fail to increase the SID.

Metabolic Alkalosis

Metabolic alkalosis is defined as an elevation of plasma HCO_3^- with an arterial pH above 7.45. There is no accurate estimate of the incidence or prevalence of metabolic alkalosis. However, in the critical care setting, it is estimated that metabolic alkalosis is the more common form of acid-base disorder, as it may be present in about 50% of all acid-base disorders. A study in pediatric patients undergoing open-heart surgery found that 72% of children younger than 12 months of age developed metabolic alkalosis, in contrast with 30% of those older than 12 months of age. It is difficult to attribute a figure of mortality or morbidity directly to metabolic alkalosis. However, at least one study in adults found that mortality progressively rose with the pH: 47% with pH 7.57 to 7.59, 65% with pH 7.60 to 7.64, and 80% with pH 7.65 to 7.70.[307,308] An increased incidence of metabolic alkalosis in patients with severe sepsis and trauma is due to factors related to a vigorous correction of shock, hypotension, and acidosis, where large quantities of citrated blood or lactated Ringer solution are given, as well as the administration of bicarbonate itself[307] (Table 76.9). Other subsets of patients may arrive to the PICU with preexisting metabolic alkalosis associated with the chronic use of diuretics, excessive exogenous or endogenous steroids, high-dose antacids, elevated gastrointestinal fluid losses (emesis, suction, or chloride-rich diarrhea), and a posthypercapnic state, the typical pattern of a chronic lung disease after the resolution of an acute episode of decompensation.[308,309] Alkalemia has been classified as mild (pH 7.45-7.50), moderate (pH 7.50-7.55), or severe (pH >7.55).[307]

TABLE 76.9

Causes of Respiratory Acid-Base Derangements

Acidosis (↑ $PaCO_2$)	Alkalosis (↓ $PaCO_2$)
Central nervous system depression:	**Hypoxemia:**
Severe head trauma, brain edema, metabolic diseases, infectious diseases, intentional sedation, pharmacologic effect of drugs	High altitudes, pulmonary disease
Neural (peripheral), muscular, and skeletal structures:	**Pulmonary disorders:**
Electrolyte disturbances: hypophosphatemia, hypokalemia	Pneumonia, interstitial pneumonitis, fibrosis, edema, pulmonary embolism, vascular disease, bronchial asthma, pneumothorax
Specific diseases: myasthenia gravis, Guillain-Barré syndrome, spinal cord injury, Werdnig-Hoffmann disease, Duchenne muscular dystrophy, etc.	**Cardiovascular disorders**
	Congestive heart failure, hypotension
Ventilatory restriction: rib fractures and flail chest, patients with intraabdominal hypertension from ascites, from closure of congenital abdominal wall defects, etc.	**Metabolic disorders:**
	Acidosis (diabetic, renal, or lactic), hepatic failure
Lungs (airway and alveoli):	**Central nervous system disorders:**
Respiratory obstructive disease, either acute or chronic: croup, asthma, bronchiolitis, bronchopulmonary dysplasia	Psychogenic or anxiety-induced hyperventilation, central nervous system infection, central nervous system tumors
Alveolar injury: pneumonia, acute lung injury, acute respiratory distress syndrome, cardiogenic pulmonary edema	**Drugs:**
	Salicylates, methylxanthines, β-adrenergic agonists, progesterone

	Miscellaneous: Fever, sepsis, pain, pregnancy

According to the physicochemical approach, metabolic alkalosis results from an increase in SID, or a decrease in A_{TOT}, due to a lost of anions (Cl^- from the digestive tract or through the kidneys, albumin from the plasma) or rarely to an excess of cations.[199] In the classic approach to acid-base derangements, metabolic alkalosis is generated by net gain of base (primarily bicarbonate) or loss of nonvolatile acid from the extracellular fluid.[63,310] The excess of base may be gained through oral or parenteral bicarbonate administration or by the administration of other weak anions such as lactate, acetate, or citrate. Actually, however, it is the gain of strong cations (mainly sodium) that causes pH to increase. The acid deficit may be due to the hydrochloric acid loss by vomiting or enhanced renal acid excretion promoted by diuretics or aldosterone excess and is often accompanied by hypochloremia and hypokalemia.[307-309] In a similar way, it is the loss of strong anions (mainly chloride) rather than the direct loss of hydrogen ions that actually increases pH. There may also be a concurrent contraction of the extracellular fluid volume secondary to the chloride loss. Concomitant changes in the intracellular fluid do occur, including a loss of intracellular potassium along with a net gain of sodium and hydrogen. Hence metabolic alkalosis in the extracellular fluid is usually accompanied by acidosis and potassium depletion in the intracellular compartment. Bicarbonate or base loading is rarely the single cause of metabolic alkalosis, although this may transiently occur after an IV infusion of $NaHCO_3$ or an equivalent base (eg, citrate anticoagulant in transfused packed red blood cells). This situation may also occur after the successful treatment of ketoacidosis or lactic acidosis, because these organic anions are metabolized to bicarbonate, and after the resolution of hypercapnia, either permissive or as a part of unintentional respiratory acidosis, before the kidney can excrete the bicarbonate previously retained for compensation. It is generally accepted that metabolic alkalosis involves a *generative* stage, during which the relative concentration of alkali within the body increases, and a *maintenance* stage,[308,309] during which the kidneys fail to compensate by excreting strong cations and HCO_3^-. Three major factors underlie the maintenance phase in most clinical situations: (1) depletion of circulating volume, changes in generalized hemodynamics (eg, heart failure) and in intrarenal hemodynamics, which combine to reduce the filtered load of bicarbonate traversing the proximal tubule despite the increase in bicarbonate concentration; (2) increased aldosterone secretion (and probably endothelin-1), due to volume contraction and increased angiotensin-II, that stimulates acid secretion; and (3) total potassium depletion and hypokalemia, which alter glomerular hemodynamics, stimulate the renal H^+-K^+-ATPase, and secondarily increase renal acid secretion in the presence of aldosterone.[310] In other words, the regulation of pH through strong cation (mainly sodium) and bicarbonate elimination is sacrificed to preserve volume and potassium stores. If volume and potassium are normalized, metabolic alkalosis self-corrects.

Metabolic alkalosis has been classified by the primary organ system involved, the response to therapy, or the underlying disease.[309,311] In the critical care setting it may be more convenient to classify it according to the response to therapy and to use the serum chloride concentration as the key variable for this classification.[29,44,89,63,199] Sometimes the loss of Cl^- is temporary and can be treated effectively by replacing it; this type of metabolic alkalosis is known as *chloride responsive*. It represents the most

frequently encountered metabolic alkalosis in the pediatric critical care unit that is also the most severe.[307-311] These disorders are usually the result of Cl^- losses from gastric drainage or persisting vomiting, as in pyloric hypertrophy and other causes of upper gastrointestinal obstruction.[29,161,307-309] This type of metabolic acidosis also may occur as a consequence of the administration of diuretics.[44] Both persisting vomiting and excessive diuretics generate some degree of dehydration, with volume contraction and secondary stimulation of aldosterone release, which in turn leads to increased tubular Na^+ reabsorption, an alkalinizing process, because it increases the SID, and to increased urinary loss of K^+, which may result in hypokalemia.[309]

In other cases, hormonal mechanisms leading to an excess of mineralocorticoid activity directly produce ongoing losses of K^+ and Cl^-, or such a loss is associated with genetic renal tubular defects of electrolyte transport, mainly in chloride reabsorption. Decreased plasma levels of Cl^- and K^+ lead to an increased SID, which in turn yields metabolic alkalosis. In this setting, the Cl^- deficit can be offset only temporarily, at best, by Cl^- administration. Therefore this form of metabolic alkalosis is said to be *chloride resistant*[29,44,63,199,307-311] (see Table 76.9). The hallmark of this group of disorders is an increased urine Cl^- concentration, more than 20 mEq/L (usually >40 mEq/L).[307-311] Treatment requires a search for the underlying disorder and, if possible, a specific therapeutic intervention. Among the most important causes of chloride-resistant disorders are (1) the group of diseases with mineralocorticoid excess, which includes primary and secondary aldosteronism, congenital adrenal hyperplasia renin-secreting tumors, and Cushing syndrome; (2) the group of tubulopathies, including chloride wasting tubulopathies (Bartter and Gitelman syndromes) and a defective epithelial sodium channel (ENaC) leading to a decreased sodium elimination (Liddle syndrome); (3) the group of drug-induced hypokalemic alkaloses including diuretics, high-dose glucocorticoids, fludrocortisone, aminoglycosides, and the toxic effects of licorice *(Glycyrrhiza glabra);* and (4) the miscellaneous group, which includes 11β-hydroxylase deficiency, salt-losing nephropathy, cystic fibrosis, and congenital chloride diarrhea, among others.[161,308-315]

Random urine chloride determination may useful: uCl^- <20 mEq/L is consistent with chloride-responsive metabolic alkalosis; uCl^- >20 mEq/L is consistent with chloride-unresponsive metabolic alkalosis.[308-313] However, this general rule may not apply to other special causes of metabolic alkalosis, which include the extrarenal chloride-resistant forms, such as cystic fibrosis,[314] and congenital chloride diarrhea, a recessively inherited disorder of chloride transport in the distal ileum and colon.[315] In both disorders a huge extrarenal chloride loss occurs (through sweat or diarrhea), and urine chloride may be low, normal, or high, depending on the patient's renal function and the clinical situation. Finally, metabolic alkalosis may occur as the SID increases as a consequence of the gain of cations rather than strong anion depletion. The most common clinical situation in the critical care setting is the IV administration of strong cations without strong anions, such as occurs with a massive blood transfusion. In this case, sodium is administered predominantly with citrate (a weak anion) instead of chloride. A similar mechanism of metabolic alkalosis occurs when the parenteral nutrition contains excess sodium acetate (another weak anion) and insufficient chloride to balance the sodium load. The excessive infusion of some gelatins used as plasma volume expanders and sodium lactate (as in Ringer solution) can also cause metabolic alkalosis. The milk-alkali syndrome is now a rare cause of this disorder.

Treating Metabolic Alkalosis

Alkalosis and alkalemia are important because they may increase morbidity and mortality. An increase in blood pH increases neuromuscular excitability, probably related to a decrease in ionized calcium concentration and potassium shifts, leading to an alteration of consciousness, increased seizure activity, increased cardiac arrhythmias, decreased oxygen release to tissue from hemoglobin, tetany secondary to hypocalcemia, increased ammonia generation by the kidney, and, in some instances, depression of ventilatory drive. Because mortality is especially high when a pH in excess of 7.6 develops, intervention at a pH of 7.55 and greater is recommended.[307,310] Regardless of the type of metabolic alkalosis, the first step for its proper management is to moderate or stop the process that generated the problem, even if only temporarily.[307] For example, if continuation of gastric drainage is required, the loss of gastric fluid can be reduced though the administration of H_2 receptor blockers or inhibitors of the gastric H^+/K^+-ATPase. If it is not possible to withdraw diuretics, it may be possible to use potassium-sparing compounds (eg, spironolactone or amiloride), which decrease distal tubule acidification and curtail potassium excretion. The administration of bicarbonate or its precursors such as lactate, citrate, and acetate should be discontinued. If drugs with mineralocorticoid activity are being administered, their indication and dose should be reassessed.

Up to 10% of the total bicarbonate filtered is reabsorbed or lost to urine in the distal renal tubule. In most patients with metabolic alkalosis, extracellular fluid, together with chloride, potassium, and magnesium concentrations, is decreased. Hence the blood flow to the kidneys is also decreased, and secretion of both aldosterone and endothelin-1 is stimulated, bicarbonate urine loss is reduced, chloride wasting increases, and urinary hydrogen ions and potassium are reduced even more. Because potassium, chloride, and magnesium concentrations limit bicarbonate excretion, their low concentrations will make metabolic alkalosis refractory to correction. Thus the restoration of circulating volume and electrolyte composition will allow renal excretion of bicarbonate and the correction of metabolic alkalosis.[307] Or in accordance with the physicochemical approach, it really does not matter if bicarbonate excretion is enhanced, but it is the replacement of Cl^- that corrects the increased SID.[199] Saline plus KCl infusion is usually the best choice because of the typical coexisting volume depletion and hypokalemia. The administration of normal saline is effective despite the release of equal amounts of Na^+ and Cl^- because this results in larger relative increases in Cl^- concentration compared with Na^+ concentration. Patients who have developed metabolic alkalosis as a result of the effects of diuretics will be best treated by the provision of potassium chloride, because their previous treatments have rendered them potassium depleted. For renal failure patients, decreasing or adjusting the diuretic regimen, adding acetazolamide (a carbonic anhydrase enzyme inhibitor that enhances renal sodium bicarbonate loss, increasing urinary SID and decreasing blood SID),[279] and cautiously administering NaCl and potassium chloride may suffice.[307] If the pace of correction of the alkalemia needs to be accelerated, hydrochloric acid (HCl) can be infused intravenously as a 0.1 to 0.2 N solution (ie, 100-200 mmol/L of H^+). This intervention, which is rarely needed, is safe and effective for the symptomatic rapid relief of severe metabolic alkalosis. Because of its sclerosing properties and its hyperosmotic concentration, HCl must be infused through a central venous line at an infusion rate

of no more than 0.2 mmol/kg/h up to 20 to 50 mmol/h,[307] with arterial pH monitoring every hour. Calculation of the amount of HCl solution to be infused is based on a distribution volume equivalent to 30% of the body weight. Thus the HCl dosage can be calculated with either the SBE or the bicarbonate difference in a manner similar to the bicarbonate administration formula (Eq. 26 and 27):

$$\text{Total body BE} = \text{SBE} \times \text{body weight (kg)} \times 0.3 \qquad \textbf{(Eq. 28A)}$$

$$HCO_3^- \text{ “excess” (mEq)} = 0.3 \times \text{body weight (kg)} \times [HCO_3^- \text{ observed} - HCO_3^- \text{ desired}] \qquad \textbf{(Eq. 28B)}$$

In both formulas, the result is expressed in millimoles of HCl to be administered. If this intervention is contraindicated, not effective, or not available, and the alkalemia is severe with no hope of quick control, hemodialysis or hemodiafiltration can rapidly correct severe alkalemia and volume overload, but a dialysis solution low in lactate or bicarbonate must be used to prevent worsening of the alkalemia. The only specific treatment available to date for Liddle syndrome is a decreased dietary sodium intake or a sodium channel blocker, such as amiloride or triamterene.[310]

Respiratory Acid-Base Derangements

Although the underlying pathologic process may vary, the respiratory acid-base derangements always have the same mechanism: Alveolar ventilation is increased or decreased out of proportion to CO_2 production. CO_2 arises either from the cellular metabolism or by the titration of HCO_3^- by metabolic acids. Normal CO_2 production by the body (and its excretion by the lungs) is impressive: about 220 mL/min or about 317 L/day in a 70-kg adult, which is equivalent to 15,000 mmol of carbonic acid per day, compared with the 500 mmol/day of all nonrespiratory acids that are handled by the kidneys and gut.[44] Pulmonary ventilation is adjusted by the respiratory center in the brain stem in response to changes in $PaCO_2$, pH, and PaO_2, although respiratory drive can be influenced by other neural (anxiety, wakefulness) and non-neural factors (eg, exercise, muscle strength) and also can be altered in some pathologic situations (cystic fibrosis, asthma, and congenital central hypoventilation syndrome).[316] A precise and real-time match of alveolar minute ventilation to CO_2 production allows stable $PaCO_2$ levels of 35 to 45 mm Hg at sea level. Accuracy of the central control allows the body to adjust PaO_2 in compensation for alterations in arterial pH produced by metabolic acidosis or alkalosis in predictable ways (see Tables 76.2 and 76.3). When this normal respiratory system is disrupted or overwhelmed, $PaCO_2$ deviates from normal and respiratory acid-base disturbances are initiated. Respiratory acidosis is produced by CO_2 retention leading to hypercapnia (elevation of $PaCO_2$). Respiratory alkalosis is produced by hyperventilation, leading to a drop in $PaCO_2$ (ie, hypocapnia). As soon as $PaCO_2$ increases or decreases, plasma and intracellular buffers change their dissociation to

maintain a stable pH, the effect of which is fully manifested within 15 to 30 minutes. If the alteration in $PaCO_2$ is sustained for more than 6 hours, renal mechanisms induce far larger changes in bicarbonate concentration, reaching maximal impact within 3 to 5 days. These renal effects lead to a new steady state for the pH. The two responses to the primary alterations in $PaCO_2$, plasma plus tissue buffers and the renal response, permit description of the respiratory acid-base derangements into acute and chronic phases.[44,63,19]

Respiratory Acidosis

Respiratory acidosis occurs whenever the CO_2 elimination by the lungs is lower than the CO_2 production by the tissues, resulting in a positive balance of CO_2, which in turn increases $PaCO_2$ to a new equilibrium. Because the increase in CO_2 production alone is not sufficient to overcome the normal ability of the lungs to increase alveolar ventilation,[44,63,199] what is central to all forms of respiratory acidosis is a failure of alveolar ventilation and CO_2 excretion to increase in response to a rising $PaCO_2$. However, an increase in CO_2 production in the face of fixed ventilation can result in respiratory acidosis and may occur in the critical care setting in patients receiving mechanical hypoventilation and a high carbohydrates load in their parenteral nutrition or in a hypoventilated patient with fever-induced acute hypermetabolism. The increase in $PaCO_2$ immediately increases both the hydrogen ion and bicarbonate concentrations in blood (Eqs. 11 to 13). The increase in $[HCO_3^-]$ occurs as a consequence of physical chemical principles and not as a consequence of an adaptive response in order to *buffer* the increase in $[H^+]$.[21,29,61] The only immediate buffering activity in hypercapnia comes from the nonbicarbonate plasma and intracellular buffers.[286] Because of the increase in bicarbonate (a weak anion), no change in the SID is produced, and thus no change occurs in the SBE. Because CO_2 is produced within the cells and can freely diffuse across the lipophilic cellular membranes, intracellular acidosis always occurs with respiratory acidosis.[286,287] If the $PaCO_2$ remains increased, active compensatory mechanisms are activated, and the SID increases to restore $[H^+]$ toward normal. Primarily, respiratory acidemia compensation is accomplished by removal of Cl^- from the plasma space. Because movement of Cl^- into the tissues or red blood cells results in a drop of intracellular pH, Cl^- must be removed from the body to achieve a lasting effect on the SID. The kidneys are the most important organs for this task. Because every chloride ion that is filtered and not reabsorbed increases the SID (and the pH), Cl^- removal by the kidney must be accurate. Again the role of ammonium in this process is preeminent, not as a hydrogen ion carrier or as a potential buffer but as a cation for the excretion of Cl^- without losing Na^+ or K.[29,96] Thus when renal function is intact, Cl^- is eliminated in the urine, and after a few days, the SID increases to the level necessary to return blood pH near 7.35. This amount of time is required by the physiologic constraints of the system, but this is not entirely a disadvantage because this rate of response is useful to avoid being oversensitive to transient changes in alveolar ventilation. In any case, the compensation results in an increased pH for any degree of hypercarbia. According to the Henderson-Hasselbalch equation (Eqs. 12 and 13), the increased pH will result in an increased HCO_3^- concentration for a given PCO_2.

Therefore the so-called adaptive increase in [HCO_3^-] to hypercapnia actually results *from* the increase in pH, and it *is not the cause of* the increase in the pH, which actually occurred from the increase in the SID as a consequence of the removal of chloride. Although the change in HCO_3^- concentration is a convenient and reliable marker for the metabolic compensation (Tables 61.2 and 61.3), it is not the mechanism.

Acute respiratory acidosis develops as a consequence of the impaired function of one or more of the three participants in the ventilatory function: central nervous system; neural (peripheral), muscular, and skeletal structures; and lungs (airway and alveoli) (see also Chapters 45 and 47). Airway and parenchymal lung disease are the most common causes of acute CO_2 retention. This last group of conditions also produces primary hypoxemia, not only hypercapnia. It is hypoxemia, not hypercapnia or acidemia, that poses the principal threat to life. Conditions that cause the failure of the lungs to eliminate CO_2 can also be grouped into two types of ventilatory disorders.[44,63,199] The first or "pure" hypoventilation occurs as a result of brain stem or neuromuscular dysfunction or because of extrapulmonary restrictive lung compromise. In this setting, the lung simply fails to move enough air in and out to exchange CO_2 and oxygen. As a result, PaO_2 falls in proportion to the rise in $PaCO_2$. In the second and more common situation in the critical care setting, alveolar hypoventilation is the result of the imbalance between perfused and hypoventilated segments of a damaged lung (ie, ventilation-perfusion [V/Q] inequality) (see also Chapter 48). In this case, a fall in PaO_2 often precedes hypercapnia, and when hypercapnia finally develops, the reduction in PaO_2 is proportionally greater than the rise in $PaCO_2$. With both types of ventilatory defects, however, hypoxemia is a concurrent finding when hypercapnia is present.[44]

Chronic respiratory acidosis is most often associated with chronic lung disease (eg, bronchopulmonary dysplasia) or chest diseases with abnormal chest wall mechanics (chest congenital deformities, kyphoscoliosis), but it can also be caused by chronic upper airway obstruction (eg, obstructive sleep apnea syndrome and craniofacial disorders),[316] chronic neuromuscular diseases, or chronic central nervous system problems (congenital central hypoventilation syndrome).[317] Respiratory decompensation in patients with these conditions usually results from recently acquired infection, use of narcotics, or uncontrolled oxygen therapy.[318] These additional factors superimpose an acute element of CO_2 retention and acidemia on the already elevated baseline CO_2. Progressive narcosis and coma (ie, hypercapnic encephalopathy) may ensue. On the basis of the preeminent renal participation in the ultimate compensation of hypercapnia, one should expect that patients with renal disease (with difficulties excreting chloride) will have a defective adaptation to chronic hypercapnia.

Treating Respiratory Acidosis

As the main threat to life in respiratory acidosis comes from associated hypoxemia, and not from the level of hypercapnia or acidemia, oxygen administration represents a critical element in the management of respiratory acidosis. Caution must be taken when uncontrolled concentrations of oxygen are administered to some patients with hypercarbia, particularly those with chronic lung disease, in whom exaggerated oxygen supplementation could depress respiratory drive and provoke a further

increase in $PaCO_2$.[318] This occurs because chronic hypercapnia is thought to down regulate CO_2 chemoreceptor sensitivity, which means that these patients are more dependent on hypoxic drive to maintain adequate spontaneous ventilation. It should be emphasized, however, that the correction of hypoxia overrides strategies to avert oxygen-related hypercapnia, which normally tends to be of small clinical significance in children. Whenever feasible, treatment of hypoventilation must be directed to the underlying cause. Sometimes it is possible to solve the primary cause of hypoventilation rather quickly (eg, relief of obstruction from croup with racemic epinephrine, reversal of narcotics with naloxone, or resolution of bronchial spasm with a β_2 agonist). Generally speaking, mechanical ventilation is indicated when the patient is at risk of instability, the patient is already unstable, or central nervous system function is deteriorating.[319] It is not the absolute value of $PaCO_2$ (or PaO_2) that is important but rather the clinical condition and perceived trajectory of the patient. If the patient is obtunded or unable to cough and if hypercapnia and acidemia are worsening, mechanical ventilation should be instituted. Application of noninvasive mechanical ventilation in children is growing both in acute situations within the ICU and in cases of chronic hypercapnic and hypoxemic respiratory failure of various causes.[320] When $PaCO_2$ is increased and minute ventilation is low, level of consciousness is generally impaired. These patients usually require intubation for airway protection in addition to ventilatory assistance, unless the hypercapnia can be quickly reversed.[321] Hypoxemia is treated with FiO_2 augmentation and recruitment of airspaces, whereas the usual ventilatory strategy for hypercapnia is to increase minute ventilation. When the ventilator is used to correct respiratory acidosis, the end-inspiratory plateau and auto-PEEP pressures should be monitored routinely to detect any adverse effects of hyperventilation. Overly rapid reduction in the $PaCO_2$ risks development of *posthypercapnic alkalosis,* with potentially serious consequences. One possible option not yet routinely available for intractable hypercapnia is intratracheal pulmonary ventilation, in which an intratracheal catheter with a reversed continuous flow of gas at its tip (away from the lungs) facilitates flushing CO_2 from the proximal dead space.[322] Another possible approach is the extracorporeal removal of CO_2 (see also Chapter 59).[323]

Permissive hypercapnia may be indicated in patients with severe ARDS to minimize ventilator-associated lung injury (see also Chapters 51 and 57).[173,324] Use of permissive hypercapnia as part of a lung-protective strategy in children should be utilized, provided it does not result in significant hemodynamic instability or there is a coexisting contraindication, such as intracranial hypertension.[324,325] It has been suggested that hypercapnia be targeted to maintain pH >7.2,[324] and this strategy appears to be safe for any age.[324-330]

In adult patients undergoing permissive hypercapnia, a pH well below 7.2 has been tolerated.[329] In terms of the limits of hypercarbia in otherwise healthy children, even transient $PaCO_2$ in the range of 200 to 300 has been tolerated without long-term sequellae.[176,331] This might not be the case for a critically ill child with multiple system involvement, particularly brain injury.[332]

Animal studies have demonstrated hypercarbic acidosis may protect against lung and systemic injury, even when instituted after the initiation of the lung or systemic

injury process.[325,329] The mechanism involving inhibition of cytokine and chemokine production seems to be mediated, at least partially, through the inhibition of nuclear factor-κB (NFκB).[325,329,333] Hypercapnic acidosis also appears to inhibit repair of pulmonary epithelial injury.[333-336]

There is evidence that the protective effects of hypercarbic acidosis in acute lung injury are more a function of the acidosis rather than of elevated carbon dioxide *per se*.[337-339] In a recent and elegantly designed animal experiment,[340] it was found that moderate hypercapnia ($PaCO_2$ 80-100 mm Hg, pH 7.13 ± 0.09) was neuroprotective after transient global cerebral ischemia/reperfusion injury. The protective effect was attributed to the modulation of apoptosis-regulating proteins. In contrast, severe hypercapnia ($PaCO_2$ 100-120 mm Hg, pH 7.05 ± 0.1) was associated with increased brain injury. These results suggest a potential role for "therapeutic hypercapnic acidosis" after global cerebral ischemia, a potential paradigmatic therapeutic change.

Respiratory Alkalosis

If alveolar ventilation rises out of proportion to CO_2 production, then $PaCO_2$ falls. For any given rate of CO_2 production, an increase in alveolar ventilation always reduces $PaCO_2$. In the ICU environment, hyperventilation occurs in a number of pathologic conditions, including salicylate intoxication, early sepsis, hypoxic respiratory disorders including early phase of ARDS, Kussmaul respiration, hepatic failure, fever, certain central nervous system alterations, and pain or anxiety. The presence of respiratory alkalosis is a bad prognostic sign because mortality increases in direct proportion to the severity of the hypocapnia.[341] The detrimental effects of hypocapnia have been described in many settings: in premature infants in whom it has been associated with poor neurologic outcome; in children after severe traumatic brain injury, in whom a relationship between hypocapnia and cerebral ischemia and infarcts have been described[341]; and in children after a cardiopulmonary bypass procedure.[342]

As in acute respiratory acidosis, acute respiratory alkalosis elicits a secondary change in plasma bicarbonate that has two components. The first is the occurrence of a small to moderate acute decrease in the bicarbonate concentration; this fall is dictated by the Henderson-Hasselbalch equation (Eqs. 12 and 13) and is also due to some tissue buffering.[29,341,343] With the persistence of the hypocapnia, the second component appears: SID will begin to decrease as a result of renal chloride reabsorption, which is associated with a larger decrease of bicarbonate and a rise in urine pH.[5,9,10,21,35,44] By 48 to 72 hours, SID assumes a new, lower, steady state. This occurs because renal adaptation to hypocapnia *backtitrates* the nonbicarbonate buffers, an action that decreases SID and tends to return pH toward normal values, usually with an increased chloride serum concentration.[21] Usually, blood pH does not exceed 7.55 in most cases of respiratory alkalosis, and severe manifestations of alkalemia are unusual. Marked alkalemia can occur in certain circumstances: inappropriate mechanical ventilation parameters, central nervous system disorders, and some psychiatric diseases, not often seen in children.

Pseudorespiratory Alkalosis

Arterial hypocapnia does not necessarily imply respiratory alkalosis or the

secondary and compensatory response to metabolic acidosis. The presence of arterial hypocapnia in patients with profound circulatory shock has been termed *pseudorespiratory alkalosis*, or simply *venoarterial carbon dioxide gradient*.[185] This condition can be seen when alveolar ventilation is relatively preserved but profound cardiovascular depression exists. In such conditions, the severely reduced pulmonary blood flow limits the CO_2 delivered to the lungs for its excretion. On the other hand, the increased ratio of ventilation to perfusion and the increased pulmonary transit time result in the removal of a larger-than-normal amount of CO_2 per unit of blood traversing the pulmonary circulation.[344] Thus despite decreased CO_2 delivery to the lungs, a situation that provokes a significant elevation of the mixed venous blood CO_2, arterial normocapnia or frank hypocapnia may be noted. Overall, CO_2 excretion is markedly decreased, however, and the CO_2 balance of the body is positive, a phenomenon that is the hallmark of respiratory acidosis. Marked tissue acidosis is reflected in mixed venous blood acidemia, usually involving both metabolic and respiratory components. The metabolic component derives from tissue hypoperfusion and hyperlactatemia. This is accompanied by an arterial pH that ranges from mildly acidic to frankly alkaline. This venous-arterial PCO_2 gradient increases as cardiac index decreases.[185,344,345] In animal models, both venous-arterial PCO_2 gradient and venous-arterial pH difference increase as oxygen delivery declines. In septic shock, an elevated venous-arterial PCO_2 gradient is seen in patients with low cardiac output and in those with pulmonary disease who cannot eliminate CO_2.[346] In patients with cardiogenic and septic shock, the venous-arterial PCO_2 gradient decreases as hemodynamic variables improve.

Mixed Acid-Base Derangements

Coexisting metabolic acidosis and respiratory acidosis can be seen in cardiopulmonary arrest, bronchopulmonary dysplasia complicated with pneumonia and septic shock, renal and pulmonary insufficiency, and as a consequence of certain toxic agents that may provoke both neural depression (and hypoventilation) and cardiocirculatory collapse (and metabolic acidosis).[44,63,90,95,199] As usual, treatment must be targeted to the underlying causes. In addition, both components of the acid-based derangement must be addressed.

Alkalemia of both metabolic and respiratory origin may occur in several complex settings, such as in patients with chronic liver disease in whom hyperventilation ensues as the initial manifestation of pneumonia.[347] This hypocapnia appears in a patient in whom metabolic alkalosis is common because of vomiting or gastric drainage, hypokalemia, diuretics, or alkali administration.[90,347] Mixed alkalosis may also occur in patients with chronic renal insufficiency in whom primary hypocapnia develops. In this setting, inappropriately high plasma bicarbonate levels occur as a consequence of the nonexistent renal adaptive response. This situation is seen despite the patient's dialysis program because the dialytic procedures are an alkalinizing influence and are much less effective in compensating alkalemia than acidemia.[348,349] This effect can be minimized by switching the patient from peritoneal dialysis to hemodiafiltration or hemodialysis.

Both the physicochemical (SIG and SID_{EFF}) and the modified SBE approaches are

well suited for unmasking coexisting, mixed acid-base disorders.

Acid-Base Balance in Special Situations: Hypothermia

Systemic hypothermia is one of the strategies employed for brain preservation and end-organ protection in global ischemia scenarios. Hypothermia is routinely applied in cardiopulmonary bypass for cardiac surgery, and thus anesthesiologists deal with most acid-base derangements during profound hypothermia in the operating room (see also Chapter 37).[350] Hypothermia can occur accidentally after near-drowning in ice water or other environmental exposures. As temperature decreases, $[H^+]$ decreases and pH increases in aqueous systems. Hence the measured pH in an electrochemically neutral cell at 37°C is 7.4, whereas in an electrochemically neutral cell at 20°C, the measured pH will be 7.8. Changes in cellular pH during hypothermia are mediated through PCO_2 homeostasis. As temperature decreases, the solubility of CO_2 in blood increases, which in turn reduces PCO_2. For example, if the total CO_2 content is held constant, and the measured PCO_2 at 37°C is 40 mm Hg, then the measured PCO_2 at 20°C will be 16 mm Hg. When a blood sample is introduced into a blood-gas analyzer, the sample is warmed to 37°C before measurement. The values obtained at 37°C are called the *temperature-uncorrected* values. These values are converted by the blood-gas analyzer to *temperature-corrected* values (actual patient's temperature) using a nomogram, which accounts for temperature-induced changes in pH, and in O_2 and CO_2 solubility. If pH and PCO_2 are measured at 37°C and then corrected to a lower temperature, the corrected pH will be higher and the corrected PCO_2 will be lower than the values at 37°C.

Alpha-stat and *pH-stat* are acid-base management methods that directly influence blood flow to the brain and other organs, and they both can be applied using either corrected or uncorrected blood gases. At a patient temperature of 37°C, there is no difference between alpha-stat and pH-stat management. The difference between these two strategies becomes apparent as patient temperature progressively decreases below 37°C and is not clinically relevant until patient temperature is around 30°C and below. Alpha-stat strategy has solid theoretic foundations. It is well known that functions of proteins are critically dependent on their tertiary and quaternary structures, which in turn depend on the ionic charges of individual amino acid constituents. Thus intracellular proteins must have a buffer of their own in order to keep a constant ionizing state in spite of pH change. The imidazole moiety of the amino acid histidine has a pK_a that is similar to the pK_a of the water, and hence it undergoes ionization with temperature changes in a similar proportion as water. The portion of the histidine imidazole group that loses a proton, acting as a buffer to maintain electrical neutrality, is designated alpha-imidazole. Thus whereas changes in temperature will affect the degree of dissociation (ie, pH) of water, the ionization state of the proteins will remain the same because it will adapt to the new temperature-influenced pH. Hence proteins will maintain their structure and function regardless of the temperature. So according to this alpha-stat hypothesis, the alpha-stat management is simple: Electrochemical neutrality is maintained by keeping pH in the alkalotic range in temperature-corrected blood gases and normal

in temperature-uncorrected gases. For practical purposes, it is easier to use uncorrected gases and make any necessary adjustment in order to keep pH at 7.4 and $PaCO_2$ at 40 mm Hg at 37°C, regardless of the patient's body temperature.

On the contrary, in the pH-stat approach, interventions are directed toward maintaining pH 7.4 and $PaCO_2$ 40 mm Hg, irrespective of patient's core body temperature. This means that the goal is to keep pH and PCO_2 at normal values for 37°C when the patient's body temperature-corrected gases are used and at acidotic values when temperature-uncorrected gases are used. For practical purposes, pH-stat is maintained by adding CO_2 to the ventilating gas during hypothermic cardiopulmonary bypass to increase PCO_2 and decrease the pH. In contrast to the alpha-stat approach, in which CO_2 content is held constant, pH-stat regulation results in an increase in total CO_2 content.

There is still debate as to whether pH-stat or alpha-stat management should be used during deep hypothermia and circulatory arrest in neonates, infants, and children. Based on the theoretic advantages of maintaining electrochemical neutrality during hypothermia, in the early 1980s the strategy at Boston Children's Hospital switched from pH-stat management to alpha-stat management. Within a short period of time, the incidence of severe neurologic injury in the form of choreoathetosis increased markedly following procedures under deep hypothermia cardiac arrest.[350,351] After this negative experience and the clinical trial that resulted from it, and on the basis of other preclinical and clinical data, the current best evidence suggests that the best technique to follow in the management of acid-base in patients undergoing deep hypothermic circulatory arrest during cardiac surgery is dependent on the age of the patient, with better results using pH-stat in the pediatric patient and alpha-stat in the adult patient.[351,352] This is not surprising, as the mechanisms of cerebral injury between adults and young children are quite different.

Summary

When one approaches a critically ill child with an acid-base imbalance, the first step is to define the nature of the disorder—that is, acidosis versus alkalosis, acidemia versus alkalemia, simple versus mixed, acute versus chronic, or severe and harmful versus neither severe nor harmful. The easiest way for screening the acid-base status is to examine the venous bicarbonate (or CO_{2TOT}) concentration. However, a normal concentration does not rule out the possibility of an acid-base derangement. So if the clinical setting suggests an illness known to be associated with acid-base imbalances, at least serum electrolytes and albumin concentrations should be obtained in order to calculate the AG_{CORR}. If the bicarbonate (or tCO_2) or AG_{CORR} is abnormal, or if a complex, potentially harmful, mixed acid-base disorder is suspected, an arterial blood analysis must be performed, which will provide information on pH, $PaCO_2$, and SBE. If possible, lactate concentration should also be obtained. This is mandatory if metabolic acidosis exists (with or without acidemia). If the presence of unmeasured anions or a mixed acid-base problem is suspected, it is advisable to calculate SID_{APP}, SID_{EFF}, and SIG, directly or through surrogates. If the patient's history documents resuscitation with large volumes of normal saline, special

attention must be given to chloride concentrations. There is compelling evidence that abnormal pH by itself may not be as dangerous as once thought. However, an individualized approach must be taken to decide if a given patient may benefit or not from modifying his or her pH and acid-base status. Finally, none of the approaches for interpreting acid-base homeostasis are without flaws. However, the physicochemical approach offers better identification and cause-related diagnosis for complex acid-base problems. Perhaps the paramount merit of this approach relates to increased awareness of the close interactions between acid-base balance and the electrolytes, anions, and cations in the body fluids.

"We are still confused—but on a much higher level" (W. Churchill).[41]

CHAPTER 77

Renal Pharmacology

Douglas L. Blowey

PEARLS

- For a goal of maintaining of a serum concentration close to the steady state throughout the dosing interval, decreasing the size of the dose while maintaining the normal dosing interval will decrease the variation between the serum drug concentration peak and trough.
- With the exception of spironolactone and arginine vasopressin antagonists, diuretics must reach the renal tubular fluid to produce a pharmacologic effect.
- Loop diuretics decrease sodium reabsorption by inhibiting the electroneutral $Na^+/K^+/2Cl^-$ cotransporter located in the ascending limb of Henle.
- Spironolactone prevents the binding of aldosterone to a cytosolic receptor resulting in a decrease in the number of apical sodium channels.
- Continuous infusion of a loop diuretic is more efficient than intermittent high doses and avoids the high and low serum concentrations associated with toxicity and resistance.

The kidney plays a central role in many physiologic processes that have a direct impact on drug action and disposition, and it is also an important target for drug therapy in the critically ill child. Key functions of the kidney are elimination of endogenous and exogenous substances from the body, including drug and drug metabolites, and maintenance of body fluid composition and volume. Glomerular and tubular mechanisms that affect these functions are directly and indirectly influenced by the function of other organs. For example, congestive heart failure decreases the adequacy of arterial blood flow and is detected by sensors located throughout the circulatory system. Sensed reduction in effective arterial blood volume triggers a complex neurohormonal response that decreases kidney blood flow, increases sodium and water retention by the kidney, and further aggravates the edema associated with congestive heart failure. Conversely, the accumulation of drugs, drug metabolites, metabolic waste products, and alterations in body fluid composition and volume associated with kidney failure may have deleterious effects on the function of other vital organs and physiologic systems.

Kidney Function and Drug Disposition

Many drugs are eliminated by the kidney, and abnormal kidney function can affect the amount of drug present at the site of action and the magnitude of the drug response. Understanding of the effects of abnormal kidney function on drug disposition and action is important because abnormal kidney function is common in the critically ill child and alterations in drug disposition or action may result in suboptimal therapeutic efficacy or serious adverse events.

The pharmacologic effect of a therapeutic agent is determined by the amount, and time, that the active drug component (eg, parent drug or drug metabolite) is present at the site of action and the responsiveness of the target organ to the drug. Only the free, unbound form of a drug can exert a pharmacologic effect through interaction with receptors. Disposition of a drug after administration is determined by the drug formulation and route of administration, rate and extent of absorption from the site of administration, extent of distribution in the body fluids and tissues, rate and extent of metabolism, and rate and route of elimination. Drug disposition and response are further influenced by the genetic, physiologic, and pathologic constitution of the ill child.[1,2] Pharmacokinetics is the mathematic expression of drug disposition, and pharmacodynamics describes the magnitude of response to a drug. Determination of pharmacokinetic parameters is an invaluable tool for designing individualized drug-dosing regimens in children with kidney failure or critical illnesses that may alter drug disposition.

Although decreased kidney elimination of drugs and drug metabolites is the most obvious consequence of altered kidney function, kidney failure or the associated coexisting conditions may affect drug absorption, distribution, and metabolism (Table 77.1).[3-5] The mechanisms that govern drug removal by the kidneys are glomerular filtration, tubular secretion, and tubular reabsorption. These processes are altered in children with kidney disease, as well as other organ dysfunction. Each of the kidney's 1 million nephrons consists of a tuft of capillaries (glomerulus) enveloped by an epithelial-lined capsule (Bowman space) that drains into a contiguous tubular system (see also Chapter 72). As blood flows through the glomerular capillaries, fluid and small solutes, including drugs and drug metabolites not bound to plasma proteins, pass through the glomeruli into the Bowman space. The volume of water and accompanying solute that is filtered through the glomeruli per unit time is the glomerular filtration rate (GFR) and is the most important measure of kidney function (see Chapter 74). The GFR is estimated with the measurement of the rate that the kidney removes a substance from the blood (eg, renal clearance). The measured substance may be an endogenous compound (eg, creatinine [Cr] or cystatin C), an exogenous compound that is specifically administered to measure the GFR (eg, inulin, isotope, or iohexol), or a compound primarily eliminated by glomerular filtration that is administered as part of clinical care (eg, gentamicin).[6] The clearance of Cr corrected for body surface area is the most common method used to estimate the GFR. Creatinine clearance (C_{Cr}), expressed in mL/min/1.73 m^2, is calculated with the measurement of the amount of Cr in an accurately timed urine collection and a midcollection plasma Cr.

$$C_{cr} = \frac{[\text{Urine CR (mg/dL)} \times (\text{Urine volume [mL]/Time [min]})]}{\text{Plasma Cr (mg/dL)}} \times \frac{1.73\ \text{m}^2}{\text{BSA (m}^2)}$$

C_{Cr} is low at birth and rapidly increases during the first 2 weeks of life, followed by a steady rise until adult values are reached by 8 to 12 months.[7,8]

TABLE 77.1

Potential Alterations of Drug Distribution in Kidney Failure

PK Parameter	Effect	Proposed Mechanism
Absorption	↓	Edema of GI tract, uremic N/V, delayed gastric emptying Drug interaction—phosphate binders, H_2 blockers Altered GI pH
Distribution	↑	Increased unbound drug fraction Hypoalbuminemia (nephrosis, malnutrition) Uremic changes in albumin structure
Metabolism	↓ ↑	Inhibition of CYP-450 metabolism (liver, intestine, kidney) Drug interaction Direct inhibition by "uremic" milieu Induced CYP-450 metabolism
Excretion	↓	Decreased GFR Decreased tubular secretion Increased tubular reabsorption

CYP-450, cytochrome P-450; *GFR*, glomerular filtration rate; *GI*, gastrointestinal; *N/V*, nausea and vomiting; *PK*, pharmacokinetic.

Although not as accurate as a timed urine collection, for children aged 1 to 18 years, C_{Cr} can be quickly estimated with the measurement of the child's serum Cr and length with the following equation[9]:

$$C_{cr} = \frac{\text{Length (cm)} \times 0.41}{\text{Plasma Cr (mg/dL)}}$$

The total amount of drug eliminated from the body by the kidneys is a composition of the amount of drug filtered across the glomeruli, the amount actively secreted into the filtrate by the renal tubules, and the amount reabsorbed by the renal tubules. Because albumin and other large molecules do not pass through the glomeruli, large drugs and drugs bound to plasma proteins normally do not pass through the glomeruli and are not effectively removed by glomerular filtration but may be efficiently eliminated by the kidney through renal tubular secretion (eg, furosemide). For drugs and drug metabolites that are primarily eliminated by glomerular filtration, the rate of elimination mirrors kidney function (C_{Cr}). As such, when kidney function declines, the reduced drug elimination results in drug accumulation in the body. For example, gentamicin is an aminoglycoside that is eliminated primarily by glomerular filtration with an elimination half-life of around 2 hours in children and adults with normal kidney function and 4 to 12 hours in infants because of the well-characterized developmental immaturity of kidney function.[7,8] A 75% reduction of the GFR (eg, C_{Cr} = 30 mL/min/1.73 m^2) in a 5-year-old child receiving intravenous (IV) gentamicin will prolong the elimination half-life to 8

hours. Unless adjustments are made in the dosing regimen to account for the decreased kidney elimination, gentamicin will accumulate to toxic serum concentrations (Fig. 77.1).

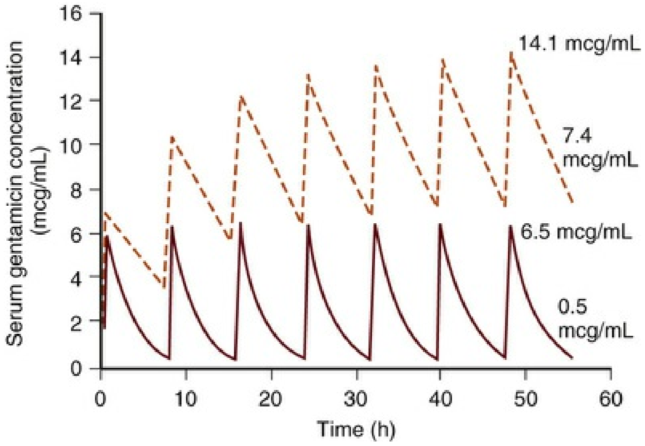

FIG. 77.1 Gentamicin time-concentration profile in a 5-year-old child receiving 2.5 mg/kg intravenously every 8 hours. The *solid line* represents the plasma concentration-time profile in a child with normal kidney function (eg, 120 mL/min/1.73 m^2) and the *dashed line* represents the plasma concentration-time profile in a child with a creatinine clearance of 30 mL/min/1.73 m^2.

Active renal tubular secretion of drugs and drug metabolites by relatively nonspecific anionic and cationic transport systems in the proximal tubule can contribute substantially to the amount of drug eliminated by the kidney. Renal tubular secretion of a drug may be inhibited by other drugs or endogenous substrates that use the same nonspecific transport systems. For example, probenecid blocks the tubular secretion of many drugs by the organic anion transporter and is useful as an adjuvant to antibiotic therapy and the prevention of drug-induced nephrotoxicity.[10-12] Coadministration of probenecid and penicillin-type antibiotics results in higher and more prolonged serum penicillin levels because of the inhibition of penicillin secretion by the renal tubule. The resultant increased penicillin exposure may enhance its therapeutic efficacy.[13,14] Nephrotoxicity is the major dose-limiting adverse effect of the antiviral agent cidofovir that is in part mediated by the proximal tubular transport of cidofovir by the organic anion system. Coadministration of probenecid restricts the proximal renal tubular uptake of cidofovir and decreases nephrotoxicity.[11] Reabsorption is the passive diffusion of nonionized (noncharged) drug from the filtrate into the renal tubular cell. Basic urine (eg, urine pH >7.5) favors the ionized form of acidic drugs and limits reabsorption, whereas reabsorption of basic drugs is enhanced in basic urine because the nonionized form of the drug is favored. Urinary alkalinization is used to enhance the renal elimination of salicylates and possibly barbiturates in overdose situations (see Chapters 127 and 128).[15]

Drug Dosing in Kidney Disease

Serum drugs and drug metabolites that are predominantly eliminated by the kidney

will accumulate in patients with impaired kidney function if adjustments are not made to the dosing regimen. A systematic approach to individualized drug therapy in children with kidney failure will ensure maximal therapeutic efficacy and minimize toxicity (Box 77.1). Designing a rational individualized dosing regimen begins with an estimation of the child's kidney function with measurement of the C_{Cr} as described in the previous section. The next step is to evaluate the effect of kidney failure on the drug disposition characteristics for all of the drugs prescribed to the child. Reference books such as the *Pediatric Dosage Handbook*,[16] *Physicians Desk Reference*, and *Micro Medex* are excellent beginning sources for information about drug disposition in kidney failure. Unfortunately, because there is little pharmacokinetic information about drug disposition in children with kidney failure, estimates from adult patients with kidney failure are cautiously used, keeping in mind the potential changes in drug disposition that occur with development.[17] The most important information for designing an optimal dosing regimen is the amount of drug that is eliminated by the kidneys in persons with normal kidney function. If one assumes that drug protein binding, distribution, and metabolism are not greatly altered in kidney failure, an assumption that is likely true for most drugs,[5] then a dosage adjustment factor (Q) can be estimated:

$$Q = 1 - \left[\%\ \text{excreted unchanged} \times 1 - \frac{(\text{Child's creatine clearance [mL/min/1.73 m}^2])}{\text{Normal creatine clearance (120 mL/min/1.73 m}^2)}\right]$$

Box 77.1

Guidelines for Drug Dosing in Kidney Failure

1. Estimate the glomerular filtration rate.

2. Determine the percentage of drug eliminated by the kidney.

3. Calculate the dosage adjustment factor (Q).

4. Adjust the dose size or dosing interval.

5. Monitor response.

6. Monitor the therapeutic drug (when available).

Once the need for a dosage adjustment has been established and the adjustment factor (Q) calculated, the best method of adjustment, whether it be a change in the size of the dose or the length of the dosing interval, is selected on the basis of the known relationships between the peak and trough drug concentrations and clinical response or toxicity. Fig. 77.2 illustrates the concentration-time profiles for two different IV gentamicin dosing regimens in a child with a measured C_{Cr} of 30

mL/min/1.73 m². About 95% of gentamicin is excreted unchanged in the urine, and the dosage adjustment factor is calculated as follows:

$$Q = 1 - \left[0.95 \times 1 - \frac{(30\ \text{mL/min/1.73 m}^2)}{120\ \text{mL/min/1.73 m}^2}\right] = 0.30$$

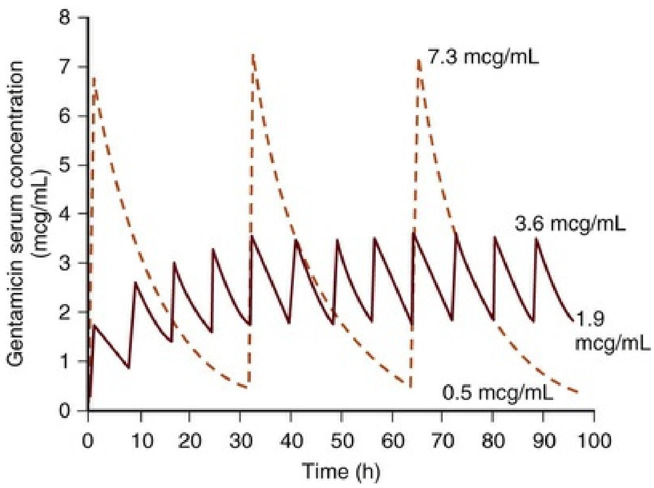

FIG. 77.2 Gentamicin concentration-time profile in a child with a creatinine clearance of 30 mL/min/1.73 m² receiving intravenous gentamicin. The *solid line* represents the plasma concentration-time profile when the dose remains unchanged (2.5 mg/kg) and the dosing interval is adjusted to 32 hours [normal dosing interval (8 hour) ÷ dosing adjustment factor (0.3)]. The *dashed line* represents the plasma concentration-time profile if the dosing interval remains unchanged (8 hours) and the dose is adjusted to 0.625 mg/kg [normal dose (2.5 mg/kg) × dosing adjustment factor (0.3)].

When the dosing interval is increased and the size of the drug dose remains unchanged (see Fig. 77.2, *solid line*), the steady-state peak and trough drug concentration are similar to those seen in children with normal renal function; however, there is a prolonged period when the serum gentamicin concentration is above and below the average steady state concentration. This dosing regimen may be inappropriate for drugs that should be maintained at a relatively stable serum concentration, such as cephalosporins or antihypertensive medications. When the goal is maintenance of a serum concentration close to the steady-state level throughout the dosing interval, decreasing the size of the dose while maintaining the normal dosing interval will decrease the variation between the serum drug concentration peak and trough (see Fig. 77.2, *solid line*). Dosing adjustments are estimates based on many assumptions, and the final step in individual therapy is close monitoring of clinical efficacy and toxicity. When available, the measurement of serum drug concentrations and determination of pharmacokinetic parameters are invaluable for individual drug therapy, especially in agents with a narrow therapeutic index.

Dialysis

Some form of dialysis is utilized in about 3% of children admitted to the intensive care unit. Drug elimination in children receiving dialysis is a composite of nonrenal drug elimination, residual kidney elimination, and the added elimination provided by dialysis. Efficiency of a given dialysis modality to eliminate a drug depends on the physiochemical characteristics of the drug and the form and characteristics of the dialysis procedure. Hemodialysis, peritoneal dialysis, and the varied forms of continuous renal replacement therapies that include continuous venovenous hemodialysis and continuous venovenous hemodiafiltration are all used in the intensive care setting (see also Chapter 78). It is beyond the scope of this chapter to detail drug disposition in the various forms of dialysis, and the reader is referred to other excellent sources for further information.[4,18] In general, highly protein-bound drugs and drugs with a large volume of distribution are not well removed by dialysis.

Kidney as a Therapeutic Target: Diuretics

Diuretics are a diverse group of drugs that act on the kidney to increase salt or water excretion. In the intensive care setting, diuretics are commonly prescribed for mobilization of excess body fluid and treatment of cerebral and pulmonary edema, ascites, and hypertension. Less common indications include congestive heart failure, disorders of calcium metabolism, glaucoma, and drug overdoses. Diuretics are grouped into six classes according to the primary site of action: Osmotic diuretics and carbonic anhydrase inhibitors act in the proximal tubule; loop diuretics act in the thick ascending limb of Henle; thiazide and thiazide-like diuretics act in the distal tubule; potassium-sparing diuretics act in the cortical collecting ducts; and vasopressin receptor antagonists act in the medullary collecting duct.

Renal tubular cells transport solute and water from the apical cell membrane (tubular fluid) to the basolateral cell membrane (blood side). Reabsorption of sodium is central to the kidney's ability to reabsorb water and other solutes (eg, glucose, amino acids, and bicarbonate). Apical cell sodium entry is mediated by channels that permit sodium to enter by diffusion or transport by specific proteins located on the apical cell membrane. In all renal tubular cells, the sodium-potassium adenosine triphosphatase (ATPase) located on the basolateral membrane maintains the low intracellular sodium concentration that favors sodium movement from the tubular fluid into the renal tubular cell. Diuretics inhibit sodium reabsorption by blocking sodium channels or sodium transport proteins located on the apical cell membrane at discrete sites along the nephron. Because sodium reabsorption occurs in a sequential manner along the nephron, the combination of diuretics with different sites of action (eg, loop diuretic plus a thiazide diuretic) has a synergistic effect on sodium reabsorption. The additional osmotic force associated with the increased urinary sodium causes a rise in urine volume. Diuresis is associated with a decrease in vascular volume that stimulates movement of sodium and water from the interstitial space into the vascular space, as well as stimulation of counterregulatory pathways (eg, the renin-angiotensin-aldosterone system) that serve to maintain an adequate extracellular fluid volume.

With the exception of spironolactone and the vasopressin receptor antagonists,

diuretics must reach the renal tubular fluid to produce a pharmacologic effect. Because diuretics are extensively bound to plasma proteins, their entry into the tubular fluid depends primarily on proximal tubular secretion. Organic anion transporters actively secrete carbonic anhydrase inhibitors, loop diuretics, and thiazide diuretics, whereas the organic cation transporters actively secrete amiloride and triamterene. Mannitol is freely filtered at the glomerulus, and spironolactone has a complex mechanism of action that does not require entry into the tubular fluid for pharmacologic effect. Finally, the nephron delivers a hypotonic fluid to the medullary collecting duct where water is either excreted or reabsorbed based on the presence or absence of apical water channels (eg, aquaporins). In response to increased plasma osmolality or reduced plasma volume, the posterior pituitary releases vasopressin into the blood that interacts with vasopressin receptors on the basolateral membrane of the collecting duct. Vasopressin mediates the insertion of water channels and the reabsorption of water (see also Chapters 81, 85).

The response to diuretics is determined by the amount and time course of drug reaching the site of action and the sensitivity of the active site to the diuretic. The concentration-response curve (Fig. 77.3) depicts the relationship between the urinary excretion rate of loop and thiazide diuretics and diuretic response. As indicated by the S-shaped curve for each diuretic, there exists a therapeutic threshold (minimal concentration) that must be reached at the site of action before any response is noted and a maximal response (ceiling) above which no further response will occur even if more drug reaches the site of action. The amount and time course of drug reaching the site of action, tubular response to the diuretic, are influenced by the route and frequency of administration, as well as drug and disease states that modify the amount of diuretic reaching the tubular fluid. An example is the twofold to threefold increase in loop diuretic dosage required for response in patients with decreased kidney function. In kidney failure, the entry of loop diuretics into the tubular fluid is limited by decreased drug delivery to the organic anion transporters due to decreased renal blood flow and competitive inhibition of diuretic transport by "uremic toxins." Adequate tubular fluid diuretic concentration and response can be achieved with the administration of high doses of diuretic,[19] but at the risk of increasing ototoxicity, particularly with concurrent aminoglycoside administration.[20,21]

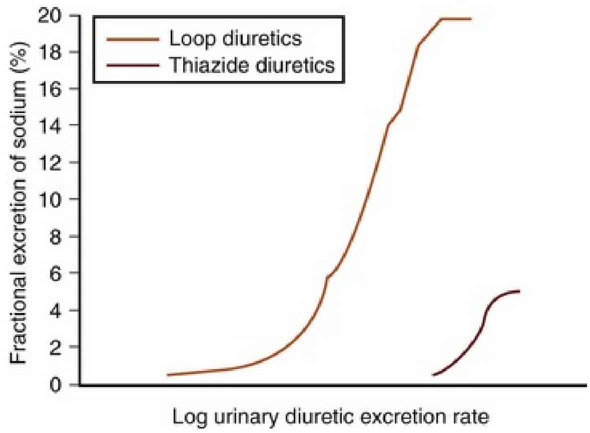

FIG. 77.3 Concentration-response curve depicting the relationship between the urinary diuretic excretion rate and the excretion of sodium in

the urine.

Loop diuretics, such as furosemide, bumetanide, and torsemide, are the most potent diuretics because a large percentage of the filtered sodium is reabsorbed (25%) in the ascending limb of Henle. Loop diuretics decrease sodium reabsorption by inhibiting the electroneutral $Na^+/K^+/2Cl^-$ cotransporter located on the apical cell membrane in the ascending limb of Henle. Loop diuretics increase sodium delivery to the distal tubular segments and diminish water reabsorption by increasing the tubular fluid osmotic force and disrupting the generation of a hypertonic medullary interstitium. The potential for profound fluid and electrolyte loss with loop diuretics mandates close monitoring of body fluid volume and serum electrolytes during therapy.

Increased delivery of sodium to the distal nephron segments has three significant physiologic consequences. First, because sodium reabsorption in the thick ascending limb results in a lumen-positive transepithelial voltage that drives passive magnesium and calcium reabsorption, inhibition of sodium reabsorption by loop diuretics diminishes the transepithelial voltage and causes an increase in the urinary excretion of calcium and magnesium. Accordingly long-term use of loop diuretics is associated with hypomagnesemia, hypercalciuria, and calcium-based kidney stones.[22-24] On the other hand, the enhanced urinary excretion of magnesium and calcium observed with loop diuretics is clinically beneficial in the treatment of hypercalcemia and hypermagnesemia.[25,26]

The second physiologic consequence of increased sodium delivery to the distal nephron segments is enhanced potassium secretion. Sodium reabsorption by the principal cell in the collecting duct favors potassium secretion into the tubular fluid and promotes hypokalemia.[27,28] Finally, the increased sodium delivery to the distal nephron is associated with acute and chronic adaptive processes that enhance distal sodium reabsorption and diminish diuretic efficacy.[29]

Loop diuretics display similar efficacy but differ slightly in pharmacokinetic characteristics. Bumetanide and torsemide are almost completely absorbed after oral administration, whereas the absorption of furosemide is extremely variable, with an average bioavailability of 50%.[30,31] Therefore when furosemide is switched from IV to oral dosing, the dose is increased to account for the decreased absorption. The onset of diuretic effect is within minutes of IV administration of a loop diuretic and 30 to 60 minutes after oral administration. The duration of diuretic effect is short (2-6 hours),[27,32,33] and this short duration often results in the need for multiple doses or a continuous infusion to achieve the desired effect.

Thiazide and thiazide-like diuretics, such as chlorothiazide, hydrochlorothiazide, metolazone, and chlorthalidone, decrease sodium reabsorption by inhibiting the Na^+/Cl^- cotransporter located on the apical membrane in the distal tubule. The thiazide diuretics are less effective than the loop diuretics (see Fig. 77.3) because less sodium reabsorption occurs in the distal tubule (5% to 10%) compared with the ascending limb of Henle. Thiazide diuretics have a synergistic effect on fluid and electrolyte excretion when combined with loop diuretics.[34-36] Thiazide diuretics have similar efficacy, and the main difference resides in potency and duration of action. Metolazone and chlorthalidone display a longer duration of effect than chlorothiazide and hydrochlorothiazide; however, the biological effect of thiazide agents is prolonged compared with their elimination rates, and thus dosing is

usually once or twice a day. Thiazide drugs are relatively ineffective in the setting of renal failure because of the decreased delivery of drug into the tubular fluid and the limited distal tubule sodium reabsorption. In contrast to the calcinuric effect of loop diuretics, thiazide diuretics enhance calcium reabsorption and may have a beneficial effect in children with nephrocalcinosis/nephrolithiasis and hypercalciuria. Thiazides have a greater propensity than other diuretics to cause hypokalemia.

The potassium-sparing diuretics triamterene and amiloride decrease sodium reabsorption by blocking the apical membrane sodium channel in the principal cells of the cortical-collecting duct. Sodium reabsorption in the cortical-collecting duct results in a transepithelial voltage that favors the secretion of potassium and hydrogen ions. Although potassium-sparing diuretics can enhance diuresis, particularly in patients receiving loop or thiazide diuretics, the main clinical benefit of these agents is a reduction in the potassium excretion induced by loop and thiazide diuretics. Spironolactone prevents the binding of aldosterone to a cytosolic receptor, resulting in decreased activity of Na^+/K^+ adenosine triphosphatase and a decrease in the number of apical sodium channels. Spironolactone is effective in primary and secondary hyperaldosteronism (eg, liver disease). Potassium-sparing diuretics are not recommended in patients with renal failure because of the propensity for the development of hyperkalemia.

Osmotic diuretics are nonelectrolytes that are freely filtered at the glomerulus and poorly reabsorbed or, in the case of glucose, present in amounts that exceed the tubular reabsorptive capacity. Mannitol is the prototypical osmotic diuretic, and its therapeutic effectiveness is directly related to the mannitol dose being large enough to raise the plasma and tubular fluid osmolality. Extraction of water from the intracellular compartments to the extracellular fluid volume that is associated with mannitol administration is clinically useful in cerebral edema, glaucoma, and the prevention of dialysis dysequilibrium syndrome. Mannitol-induced expansion of the extracellular fluid volume may be sufficient to perpetuate congestive heart failure, pulmonary edema, and significant hyponatremia in patients with renal failure in whom the half-life of mannitol is prolonged and the ability to excrete free water is limited.[37]

Carbonic anhydrase catalyzes the dehydration of carbonic acid to water and carbon dioxide, as well as the reverse hydration reaction. Acetazolamide is the prototypical carbonic anhydrase inhibitor and is more clinically useful for its extrarenal effects than its diuretic effects. Acetazolamide is used to treat glaucoma, acute mountain sickness, and occasionally epilepsy. The effectiveness of the carbonic anhydrase inhibitor is limited by the metabolic acidosis that develops because of the bicarbonate loss in the urine.

Vaptans (eg, conivaptan) are nonpeptide arginine vasopressin antagonists that inhibit the arginine vasopressin–stimulated absorption of free water in the medullary collecting duct. In contrast to other diuretics, the vasopressin antagonists increase urine flow without increasing the renal elimination of sodium. Conivaptan has been used in patients with euvolemic, or hypervolemic, hyponatremia associated with the inappropriate secretion of antidiuretic hormone or congestive heart failure.[38]

Diuretic Resistance

An inadequate diuretic response results from disease- or drug-related alterations in diuretic pharmacokinetics or pharmacodynamics, high dietary salt intake,[39] or adaptive processes[29] (Box 77.2). During diuretic-induced extracellular volume depletion, short-term and long-term adaptive processes protect the intravascular volume; however, when these adaptive processes interfere with the diuretic responsiveness before the desired reduction in the extracellular fluid volume is achieved, they contribute to diuretic resistance.

Box 77.2

Causes of Diuretic Resistance

Noncompliance

- Medication, salt restriction

Poor absorption of medication

- Poorly absorbed formulation (eg, furosemide oral)
- Disease-induced changes in absorption

Impaired excretion of diuretic

- Renal failure, renal transplant
- Drug interactions: NSAIDs, probenecid

Protein binding in renal tubule

- Nephrotic syndrome

Hemodynamic

- Shock, hypoxemia
- Drugs: NSAIDs, antihypertensive drugs

Change in dose response

- CHF, nephrotic syndrome, cirrhosis

Adaptive responses

CHF, congestive heart failure; NS, nephrotic syndrome; NSAID, nonsteroidal

anti-inflammatory drug.

Short-term adaptation results from enhanced postdiuretic sodium retention. The brisk diuresis associated with diuretics activates counterregulatory pathways that enhance sodium reabsorption and maintain extracellular fluid volume. Counterregulatory mechanisms involved in the short-term adaptation to diuretics include a decrease in atrial natriuretic peptide, increased renal sympathetic activity, increased antidiuretic hormone, stimulated renin-angiotensin-aldosterone system, and a reduced GFR. The balance favors sodium and water excretion when the diuretic concentration in the renal tubular fluid is sufficient to inhibit sodium reabsorption. When the concentration of diuretic in the tubular fluid is below the threshold needed to elicit sodium excretion, the balance favors sodium and water reabsorption. In patients receiving a generous salt intake, which may be either dietary or associated with obligate fluids or medications, the postdiuretic sodium reabsorption may compensate entirely for the diuretic-induced sodium losses, resulting in no change in the extracellular fluid volume. Long-term adaptation occurs after several days of diuretic use and is characterized by a diminished response to each successive dose of diuretic.[39] Adaptation occurs because of the persistence of short-term counterregulatory mechanisms, as well as functional and structural changes that enhance the sodium reabsorptive capability of the distal tubule.[40,41]

If the response to moderate doses of a diuretic fails to be adequate in patients, several dosing strategies may help overcome the apparent diuretic resistance including high-dose diuretic therapy, combination diuretic therapy, or a continuous diuretic infusion (Box 77.3).

Box 77.3

Intensive Diuretic Therapy

1. High-dose diuretic therapy
2. Combination of diuretic therapy
3. Continuous infusion diuretic therapy

In patients with edema, the dose-response curve may be shifted to the right, indicating that a greater amount of drug is needed in the renal tubule to produce the desired diuretic response. In patients who have renal failure or patients who receive drugs that inhibit the secretion of diuretic from the blood into the renal tubule, the dose-response curve is normal, but the problem lies in the inability to get a sufficient concentration of diuretic into the renal tubule. In both situations, an intermittent high-dose diuretic regimen may overcome the impaired rate of tubular secretion and increase the urinary diuretic concentration sufficient to elicit a response. High-dose therapy is associated with an increased risk of fluid and electrolyte abnormalities and a risk of toxicity related to high blood concentrations. Loop diuretic ototoxicity is more common with rapid infusion of high doses, especially when furosemide is combined with other ototoxic drugs.[36]

Because sodium reabsorption in the kidney is sequential and many of the adaptive processes increase sodium reabsorption distal to the site of diuretic action, combination therapy with diuretics that inhibit the distal tubule with loop inhibitors may be effective. Part of the effectiveness of combination diuretic therapy resides in the longer duration of effect for thiazides that prevents the postdiuretic sodium reabsorption noted with the shorter-acting loop diuretics. Fluid and electrolyte abnormalities are more common with combination drug therapy (Box 77.4).

Box 77.4

Common Adverse Effects Associated With Diuretics

1. Volume depletion

2. Electrolyte abnormalities

- Hyponatremia
- Hypokalemia (loop and thiazide diuretics)
- Hypomagnesemia (loop diuretics)
- Hypercalciuria (loop diuretics)
- Ototoxicity (loop diuretics, especially furosemide)

The final strategy to overcome diuretic resistance, continuous infusion of a loop diuretic, is more efficient than intermittent high doses and avoids the high and low serum concentrations associated with toxicity and resistance.[42-45] Continuous infusions result in steady diuretic effect and may avoid the rapid hemodynamic changes and stimulation of counterregulatory processes associated with rapid changes in extracellular fluid volume. A loading dose of diuretic is recommended at initiation and with each upward dosing adjustment to ensure a prompt response. Diuretic response may be further augmented by the addition of a distally acting diuretic.

Prevention/Reversal of Acute Renal Failure

Acute renal failure in the pediatric intensive care unit is generally associated with diminished renal perfusion caused by hypovolemia, hypotension, or decreased cardiac output. In addition, acute renal failure is also associated with nephrotoxins such as radiocontrast agents, antibiotics (eg, vancomycin), and chemotherapeutic agents (eg, cisplatin). With the exception of simple saline hydration, little evidence suggests that in humans, mannitol, furosemide, or dopamine prevents the development of acute renal failure in high-risk patients or changes the outcome in patients with established acute renal failure.[46-49] Nevertheless, the use of high-dose

furosemide alone or in combination with low-dose dopamine might increase urine output and ease patient care by improving fluid management and permitting increased nutrition.

CHAPTER 78

Pediatric Renal Replacement Therapy in the Intensive Care Unit

Raj Munshi, Jordan M. Symons

PEARLS

- Patients receiving renal replacement therapy require careful monitoring of fluid and electrolyte balance and nutritional needs.
- Coordination between the critical care and nephrology staff is essential for the successful care of patients requiring renal replacement therapy.
- Earlier initiation of renal replacement therapy may improve outcome.
- Peritoneal dialysis remains an excellent form of acute pediatric renal replacement therapy.
- Hemodialysis is the modality of choice for rapid correction of fluid or metabolic imbalance.
- Continuous renal replacement therapy can establish and maintain fluid and metabolic control in unstable patients.

Renal replacement therapy (RRT) has an established role in the pediatric intensive care unit (ICU).[1] Indications for RRT include volume overload, azotemia, electrolyte and metabolic imbalance, intoxication, or inability to provide adequate nutrition due to renal compromise. Acute kidney injury (AKI), however severe, is highly correlated with poor outcome in hospitalized adults and children (see also Chapter 75).[2-5] In pediatric patients, studies demonstrate increased mortality in critically ill children with excessive fluid overload with concomitant AKI.[6-10] These observations, coupled with advanced capabilities for renal replacement therapy and growing evidence that early supportive therapy may improve outcomes, lead many clinicians to consider early initiation of renal support.[11-13] Earlier intervention, either with renal replacement therapy or perhaps through careful conservative management, may prevent complications associated with serious metabolic disarray and volume overload and permit vigorous nutritional and medical support.

Although all modalities of renal replacement therapy can correct these abnormalities, certain modalities may be better suited for specific pediatric clinical situations. To date, there is no evidence that the choice of RRT modality has an effect on mortality.[14-17] However, growing evidence favors continuous renal replacement therapy (CRRT) as compared to intermittent renal replacement therapy for renal recovery.[18,19]

Basic Physiology of Dialysis and Ultrafiltration

The physical principles of molecular movement across a semipermeable membrane underlie peritoneal dialysis, hemodialysis, and CRRT modalities. The following brief review summarizes the basic mechanisms of particle and water removal for all forms of renal replacement therapy.

Diffusion describes the movement of dissolved particles across a semipermeable membrane from an area of high concentration to an area of low concentration (Fig. 78.1). This physical principle operates in all renal replacement modalities in which dialysate is used. Diffusion favors the movement of smaller particles and is most rapid when the concentration gradient across the semipermeable membrane is greatest; diffusion stops when the concentrations achieve equilibrium.

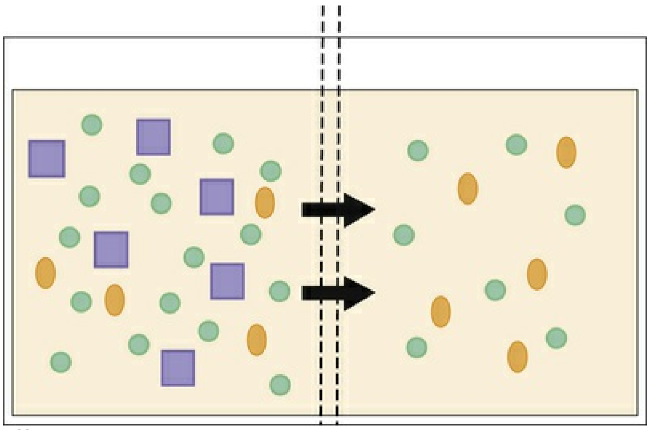

FIG. 78.1 Diffusion. Particles move across the semipermeable membrane from an area of higher concentration to an area of lower concentration. Smaller particles diffuse more freely, whereas larger particles are relatively restricted.

Convection occurs when dissolved particles pass across a semipermeable membrane because of the effects of a pressure gradient (Fig. 78.2). Particles that are smaller than the pores of the membrane can pass freely, whereas larger particles are restricted. Because particles and water are moving together, the removed solution is isotonic to the original.

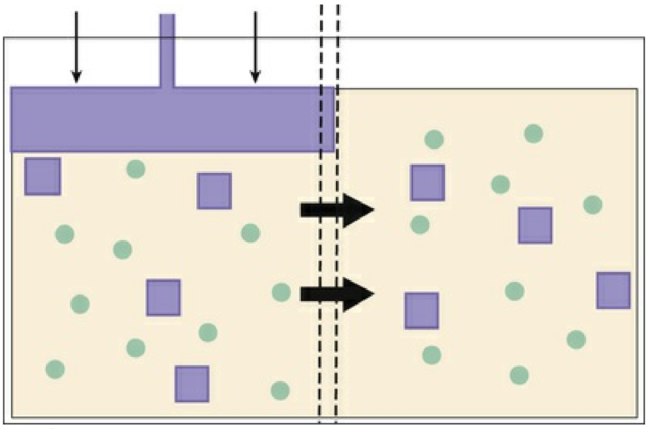

FIG. 78.2 Convection. Particles move across the semipermeable membrane, carried by ultrafiltered water, because of the effect of pressure. All particles up to the cutoff size of the membrane move relatively equally. The concentration of the effluent is equal to that of the original solution.

Ultrafiltration describes the movement of water across the semipermeable membrane due to pressure. Convection occurs with ultrafiltration.

Peritoneal Dialysis

Peritoneal dialysis (PD) has been successfully used as a therapy for AKI since 1946.[20] It is a frequent choice for chronic dialysis support, especially in children. There has been a shift in developed countries of using hemodialysis and hemofiltration for renal replacement therapy in AKI,[21] though observational studies in children and systematic review in adults show no difference in mortality between PD and hemodialysis and hemofiltration.[22-24] Today acute PD is a modality most often used in the developing world where its simplicity, effectiveness, and low cost make it attractive.[25] PD is also the ideal modality in patients with difficult vascular access and in those where the risk of complication from anticoagulation therapy is significant. Early initiation of PD in children, especially infants, who suffer AKI following cardiac surgery has been associated with improved outcomes.[26-28]

Physiology

It has been known for many years that the peritoneum can be used as a dialyzing membrane.[29] Instillation of dialysate into the peritoneal space permits diffusion of particles out of the blood and into the fluid across the peritoneum, which acts as a semipermeable membrane. Hypertonic solution, causing an osmotic gradient, generates an ultrafiltrate. Water movement will also tend to drag particles across the peritoneum by convection. After the dwell is complete, the spent dialysate is drained from the abdomen and fresh dialysis fluid is introduced.

Indications

PD can remove excess fluid and provide volume control in patients with oligoanuria. Compared with fluid removal by intermittent hemodialysis, fluid removal with PD is much slower. Manipulation of dialysis fluid osmolality and dwell time can adjust

the quantity of volume removed. The slow, steady ultrafiltration achieved with PD may be preferable to the rapid fluid removal that occurs in intermittent hemodialysis, particularly in hemodynamically unstable, critically ill patients.

Similar to volume control, PD provides slow and relatively continuous metabolic control. It is an effective method for correction of uremia. Manipulation of the PD prescription can improve molecular clearance.

Technique

The basic technique for PD involves instilling a sterile dialysate into the peritoneal cavity and allowing it to dwell for a specified period, during which particles diffuse across the peritoneal membrane and water moves across by ultrafiltration. At the end of the dwell time, the fluid is removed from the peritoneal space and the process is repeated.

Flexible catheters are most often used for chronic PD in pediatric patients. For acute PD, either this form of a surgically placed catheter or percutaneously inserted temporary PD catheters may be used. Data suggest that fewer complications occur with surgically placed catheters.[30] Catheters come in a variety of sizes, depending on the size of the patient. Local practice often determines who will insert the catheters when they are needed; the procedure requires expertise to ensure proper functioning of the catheter. The International Society for Peritoneal Dialysis recommends a surgically placed Tenckhoff catheter, currently the most utilized flexible PD catheter.[31]

PD fluid comes in standardized, sterile bags with premixed formulations; pharmacy preparation is usually unnecessary. The solutions consist of electrolytes (such as sodium, calcium, magnesium), dextrose as the primary osmotic agent, and base (either lactate or bicarbonate). Lactate absorption can lead to confusion regarding acid/base interpretation, especially in critically ill infants. In such settings bicarbonate-based dialysis fluid may be preferable,[32] although this fluid may require extemporaneous preparation by the local pharmacy, as premade solutions that use bicarbonate as a base are not available in all countries.

Ultrafiltration in PD is accomplished by osmotic pressure, usually through the presence of dextrose in the dialysis fluid. Peritoneal dialysate contains standardized concentrations of dextrose; the choices vary somewhat between the United States and other countries. Dialysate with higher concentrations of dextrose yields greater ultrafiltration for each exchange of fluid.

Peritoneal dialysate should be warmed to body temperature before instillation. This step is particularly important in small patients, in whom cold dialysate infusion can cause hypotension.

Initial exchanges with a new PD catheter should use relatively lower volumes of dialysate (10 to 20 mL/kg; <500 mL/m^2) to limit the chance of leakage from the catheter entrance operative site. Volumes may increase gradually during the next few days or weeks to 30 to 40 mL/kg; 800-1100 mL/m^2.[33]

Longer dwell periods between exchanges provide more time for equilibration of dialyzable particles and for ultrafiltration. Although shorter dwell times may not maximize mass transport for given dwell periods, they may permit more dialysis and ultrafiltration in a 24-hour period by allowing more exchanges per day. Initial dwell periods of 30 to 60 minutes can be adjusted later on the basis of clinical status.

PD fluid can be instilled by hand (manual PD) or with the use of a cycler (automated PD), a device that will automatically fill and empty the patient's abdomen with dialysate on a preprogrammed schedule. The cycler also contains a warmer for the fluid and monitoring systems to record effluent volumes. Several brands of cyclers are currently available. Programming limitations may prevent the use of a cycler for some patients who require very small fill volumes or very short dwell times.

When solute clearance or ultrafiltration is suboptimal with conventional PD or the patient cannot tolerate high fill volumes, one may consider the technique of continuous flow peritoneal dialysis (CFPD). CFPD requires two dialysis catheters placed in the peritoneum, one for inflow and the other for outflow of peritoneal fluid.[34] There is no dwell time per se as the peritoneal fluid is in constant transit through the peritoneum. CFPD can result in a fivefold increase in clearance and a ninefold increase in ultrafiltration.[35] Experience with CFPD is limited and it cannot at this time be considered a standard technique in pediatrics, although it may hold promise in the future.

Disadvantages and Complications

The PD technique requires placement of a peritoneal catheter and a sufficiently maintained intraabdominal status to permit infusion of dialysate with successful diffusion and ultrafiltration. Patients who have undergone an abdominal operation or have had abdominal complications may be poor candidates for PD.

Invasion of the peritoneal space puts the patient at risk for peritonitis, a potentially serious complication. The importance of sterile technique when performing PD cannot be overemphasized. Appropriate technique limits the risk of infectious complications, which could be fatal in a critically ill patient, but does not eliminate the risk.

Peritonitis must always be considered in a patient undergoing PD who has a fever or cloudy effluent. Dialysate should be analyzed for cell count, Gram stain, and bacterial culture if infection is suspected. Empirical or specific antibiotics can be placed in the dialysate to treat peritonitis via the intraperitoneal route.[36]

Dialysate can fail to fill or drain through the PD catheter because of a number of potential problems, including kinking of the catheter, fibrin plugs, omental obstruction, and catheter malposition. Percutaneously inserted temporary dialysis catheters are more prone to malfunction than are surgically placed catheters.[37] Abdominal x-ray images can confirm appropriate positioning and permit checks for kinks in the catheter. Some success has been reported with thrombolytic agents to treat fibrin plugging.[38-40] Revision or replacement of the catheter may need to be considered if simple maneuvers do not correct the malfunction.

Perforation of abdominal or pelvic structures can occur, either at the time of initial catheter placement or later.[37] Although this event is relatively uncommon, significant morbidity can result.

PD is a suboptimal choice for patients who require rapid correction of metabolic abnormalities, immediate removal of circulating toxins, or rapid ultrafiltration for acute complications of fluid overload. For the latter indications, hemodialysis would be the preferred modality. Effectiveness of PD may be suboptimal in settings of low cardiac output where splanchnic circulation is compromised. However, this does not

preclude the use of PD in selected cases, such as for infants following surgery for congenital heart disease.[26-28]

Fluid leakage is seen most often with dwell volumes that are too large, especially in the period immediately after catheter placement.[41] Lower fill volumes should be used. Fluid leakage into the thorax can compromise respiration. External fluid leakage around the catheter increases the risk of infection.

Intensive Care Unit Issues

Patients undergoing PD can lose protein into the dialysate. Nutritional support must provide sufficient protein to compensate for this loss. High dextrose concentrations in the dialysate can cause hyperglycemia; administration of insulin may be necessary. Indwelling dialysis fluid causes increased intraabdominal pressure that can complicate care of the critically ill patient. Diaphragmatic excursion may be limited and venous return can be reduced. Stomach compression can lead to gastroesophageal reflux. Although patients undergoing long-term PD who receive fewer daily exchanges usually require maximal fill volumes to achieve adequate dialysis, patients undergoing short-term PD may do better using submaximal fill volumes with more frequent exchanges provided around the clock.

Intermittent Hemodialysis

Intermittent hemodialysis (IHD) is a well-established technique for pediatric patients.[42] IHD offers the advantage of high efficiency for rapid metabolic correction and fluid removal. Efficient fluid and toxin removal requires rapid blood and dialysate flow. Factors that prevent achievement of high blood flow include systemic hypotension and a narrow vascular access. IHD for infants and small children can be technically demanding due to access difficulties and relatively large extracorporeal blood volume. IHD may be the preferred modality for some critically ill pediatric patients that require rapid removal of a specific toxin; successful treatment in this setting requires experienced personnel.

Physiology

The dialyzer used in IHD is an artificial semipermeable membrane. The most common design used today is the hollow-fiber dialyzer. It consists of a plastic cartridge traversed by several thousand thin hollow fibers, each with microscopic fenestrations that permit the passage of water and other small molecules. Dialyzers vary in surface area, permeability, priming volume, and membrane composition; numerous dialyzers are available commercially. Choosing different dialyzer characteristics permits adjustment of the dialysis prescription to the clinical situation.

While blood flows through the hollow fibers of the dialyzer, dialysate flows through the cartridge in the space surrounding the hollow fibers. Particles move by diffusion from the blood across the semipermeable membrane into the dialysate. Use of high-flow dialysate with maximal blood flow through the dialyzer permits intermittent hemodialysis to remove particles more efficiently than any other renal replacement therapy.

Increasing blood flow, dialysate flow, or dialyzer size will increase the rate of diffusion. Because diffusion favors the movement of small particles over large particles, large molecules or small molecules bound to larger molecules (such as albumin) will not dialyze well. In addition, intracellular particles will move into the vascular compartment on the basis of individual cell membrane transport characteristics, which may limit the rate at which dialysis can remove particles that do not reside within the vascular compartment.

Ultrafiltration on hemodialysis occurs because of hydrostatic pressure across the membrane that forces water out of the blood. Dissolved particles will travel with the water, leaving by convection. With use of IHD, dialysis staff can control the rate of ultrafiltration with precision and can achieve high rates of ultrafiltration.

Analogous to the process of diffusion, ultrafiltration during IHD removes fluid only from the vascular compartment. Extravascular or "third space" fluid must move into the vascular compartment for removal by ultrafiltration. When the rate of movement from the extravascular space is slower than the rate of ultrafiltration, intravascular depletion can occur even though total body water remains elevated (Fig. 78.3). This "two-compartment" model represents a potential limitation of rapid ultrafiltration during IHD, especially in the critically ill patient.

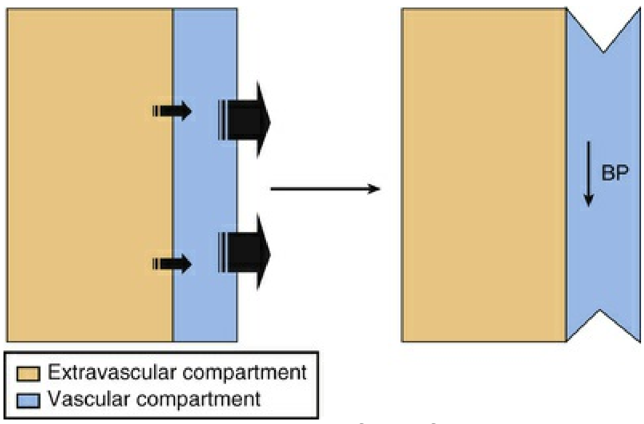

FIG. 78.3 Two-compartment model of ultrafiltration. The rate of water removal from the vascular compartment by ultrafiltration *(large arrows)* exceeds the rate of refilling from the extravascular compartment *(smaller arrows)*, and this process leads to relative vascular volume depletion and hypotension.

Indications

Due to its high efficiency, hemodialysis is the best modality for rapid particle removal. IHD is indicated for the treatment of toxic ingestions, many serious drug overdoses, and metabolic derangements that lead to the overproduction of endogenous toxins such as ammonia (see Chapters 82 and 128).[43-46]

The IHD system can perform ultrafiltration more rapidly than any other renal replacement modality. Consequently it is often the best choice for the treatment of critical volume overload but may be limited by the patient's ability to tolerate rapid fluid removal. Technology to guide ultrafiltration by the noninvasive monitoring of hematocrit changes during IHD may prevent or mitigate hypotension associated

with ultrafiltration.[47]

Profound metabolic imbalance, such as that seen with critical hyperkalemia, can be corrected most quickly with IHD. Patients with oncologic problems such as tumor lysis syndrome may require IHD to rapidly correct the multiple metabolic abnormalities and to aid clearance of uric acid, which can cause AKI (see Chapter 94).[48,49]

Technique

Vascular access is the first step for successful hemodialysis. Double-lumen catheters for hemodialysis come in a variety of sizes; occasionally, two single-lumen catheters at separate sites are needed for small infants, although data suggest that these catheters do not perform as well.[50,51] Catheters can be placed in jugular, femoral, or subclavian positions (see Chapter 19). The most desirable site for a double-lumen hemodialysis catheter is the right internal jugular vein; it provides access to a high flow area in the superior vena cava/right atrium, permits a straight venous path for the operator from insertion site to the target location, can be readily accessed for insertion of either tunneled or nontunneled catheters depending on the indication, allows ambulation and reduces discomfort for the patient as compared to the femoral site, and is less susceptible to complicating venous stenosis that will limit future permanent vascular access creation such as arteriovenous (AV) fistula. By contrast, subclavian access is associated with increased risk of stenosis that would result in loss of potential sites for AV fistula formation in the ipsilateral arm and therefore is not recommended. In neonates, umbilical catheters have been utilized if other access has failed but are often not successful due to poor flow dynamics and are not recommended.

Most patients receiving IHD will require anticoagulation therapy to prevent clotting within the dialysis circuit. Any anticoagulant can be used, with goal-activated clotting time to be 1.5 to 2 times normal if clinically appropriate. Unfractionated heparin is the most common anticoagulant used for IHD. Some may be able to undergo successful dialysis with little or no heparin because of coagulopathy related to their systemic disease. If regional anticoagulation (anticoagulation of the dialysis circuit without systemic effects) is preferred, dialysate containing citrate is available.[52] The citrate in the dialysate will bind calcium locally at the dialyzer membrane, limiting clotting within the dialyzer. Monitoring of ionized calcium is not required as the concentration of citrate is low, and thus the patient is not at risk for hypocalcemia. Clinical experience thus far shows citrate containing dialysate to be effective as an anticoagulant, but some centers have found that additional reduced doses of systemic heparinization were required.[53]

The blood pump rate is chosen based on the patient's clinical status and the quality of the vascular access. In smaller patients with smaller catheters, blood pump speeds often must run at less than 100 mL/min; in infants, speeds may run as low as 25 to 50 mL/min. Larger patients can tolerate faster blood pump speeds. Higher blood flow rates permit greater mass transfer of particles out of the patient in a given period.

The chosen dialyzer should provide sufficient clearance to achieve the goals of the dialysis session. Smaller patients receive dialysis with smaller dialyzers to limit

extracorporeal blood volume and reduce the risk of dialyzer clotting with slower blood flow rates.

Small patients or those with unstable blood pressure may require priming of the IHD circuit with saline solution, albumin, or reconstituted whole blood. Dialysis machines with precise volumetric ultrafiltration control permit accurate and safe IHD in neonates and infants, for whom small inaccuracies in ultrafiltration volumes could potentially lead to severe fluid imbalances. Dialysis fluid concentrations of electrolytes can be adjusted to some extent on the basis of the clinical situation. The length of the IHD session will vary depending on the clinical situation and goals of the therapy. Mathematical models permit estimation of dialytic clearance and can be used to structure session length. The rate at which the patient can tolerate ultrafiltration is often the limiting factor in IHD for critically ill patients. Sessions may need to be extended to achieve ultrafiltration goals without significant hypotension.

Disadvantages and Complications

The principal disadvantage of IHD is the requirement for vascular access. Acceptable access can be difficult to achieve in critically ill children. Complications related to the access can include infection, bleeding, and thrombosis.

IHD's benefit of high efficiency with rapid fluid and particle removal can lead to difficulties in the ICU setting. Critically ill patients may not tolerate the rapid ultrafiltration and metabolic shifts of IHD.

Smaller patients or those with unstable blood pressure may require priming of the extracorporeal circuit to limit hemodynamic stress at dialysis initiation. For infants in whom the extracorporeal volume is relatively much larger, priming may need to be done with a blood/albumin mix, which exposes the patient to blood products.

Most IHD sessions require systemic anticoagulation with heparin, which can be difficult to manage in a critically ill child. Heparin exposure can complicate bleeding and cause heparin-induced thrombocytopenia. With careful monitoring of clotting times and circuit performance during the session, it is possible to perform IHD without any anticoagulation. Regional anticoagulation is also available with dialysate containing citrate.

Intensive Care Unit Issues

Patients receiving IHD as ongoing renal replacement therapy in the ICU require special attention to fluid and electrolyte balance. One should limit potassium and phosphorus delivery and may need to limit total daily fluids because ultrafiltration only occurs intermittently. Packed red blood cells should ideally be administered while on dialysis to dialyze off the excess potassium. Medication doses and schedule may require adjustment because of poor excretion with renal failure and subsequent rapid removal with dialysis (see Chapters 77 and 124).

Continuous Renal Replacement Therapy

CRRT is a generic term applied to several techniques of extracorporeal renal support. Similar to IHD in the use of a blood pump and hemofilter, the various subcategories

of CRRT differ in their reliance on diffusion, convection, or a combination of the two for molecular clearance.

CRRT has become more popular as a method of renal support for pediatric patients.[1,51] Technologic improvements in catheters, blood pumps, and ultrafiltration control mechanisms permit the application of CRRT to even the smallest infants.[54,55] Compared to IHD, data suggest continuous modalities of renal replacement therapy may increase the likelihood of recovery of renal function in critically ill survivors of AKI.[18,19]

Physiology

The CRRT hemofilter is similar to that used for IHD. CRRT membranes traditionally have been more porous to permit greater removal of water. Numerous hemofilters are available commercially.

Both convection and diffusion can be used to remove particles during CRRT. Dialysate allows diffusion, which favors the movement of smaller molecules. High rates of ultrafiltration will remove both small and larger particles by convection, up to the limits of the membrane. With high ultrafiltration rates to achieve better convective clearance, the patient may need to receive replacement of volume and electrolytes to compensate for that lost in ultrafiltrate.

Because of slower flow rates, the clearance achieved with CRRT may be lower than that of IHD. Continuous therapies, however, make up for this lower efficiency through the extended time of the treatment. Compared with a 3- or 4-hour IHD session, CRRT running 24 hours a day can achieve equivalent daily clearance with less metabolic variation. Newer CRRT devices can run at flow rates approaching those seen in IHD, greatly increasing the potential for rapid molecular clearance.

Nomenclature for the various subcategories of CRRT is based on the vascular access and the primary method of particle clearance (convection, diffusion, or both). Because most CRRT in pediatric patients uses a pump-assisted venovenous method, the most commonly used terms are *continuous venovenous hemofiltration* (CVVH), which uses high convective clearance requiring replacement fluids; *continuous venovenous hemodialysis* (CVVHD), which uses dialysis fluid for diffusion but minimal additional convection; and *continuous venovenous hemodiafiltration* (CVVHDF), which uses both dialysis fluid and replacement fluids for combined diffusion and high-grade convection.

Indications

As a result of the slow, continuous removal of fluid, CRRT is particularly well suited to the treatment of volume overload in critically ill patients. Whereas IHD will attempt to reach an ultrafiltration goal within a relatively short therapeutic session, CRRT allows continuous ultrafiltration that can help maintain cardiovascular stability.

CRRT is useful to maintain metabolic balance through ongoing removal of unwanted particles. Although it is less efficient than IHD, CRRT's continuous nature can avoid daily fluctuations inherent in the use of an intermittent modality. In addition, CRRT can be used as a secondary method to maintain metabolic balance after rapid correction with IHD.[56]

For patients with diminished renal function and decreased urinary output, CRRT can allow administration of the daily load of fluids and clearance required to deliver medication, nutrition, and blood products. With this modality the patient can be maintained in a more stable balance compared with IHD, in which the patient has progressive volume overload between IHD sessions and then must achieve the ultrafiltration goal in a brief treatment period.

Technique

As in IHD, successful CRRT requires adequate vascular access (see Chapter 19). Given the relatively large extracorporeal volume, smaller patients may require priming of the CRRT circuit with blood/albumin mix. In larger, more stable patients, CRRT can be initiated successfully with saline prime.

Earlier methods that entailed arteriovenous access have largely been abandoned in favor of venovenous CRRT. Older systems with adapted blood and fluid pumps linked together extemporaneously have been replaced by dedicated CRRT machinery. Several CRRT systems are available at this time; this latest generation of CRRT machines permits much greater accuracy for blood pump speed, fluid delivery, and ultrafiltration control.

Anticoagulation

Adequate anticoagulation is essential for successful CRRT. Similar to IHD, any anticoagulant can be used, with goal activated clotting time to be 1.5 to 2 times normal if clinically appropriate. Currently, most patients treated with CRRT receive systemic heparin, regional citrate, or no added anticoagulation.

Systemic heparinization has been the traditional form of anticoagulation used in CRRT. This method is proven and functions well. Disadvantages include systemic anticoagulation with risk of bleeding, risk of heparin-induced thrombocytopenia, and the need for frequent monitoring and adjustment of the heparin dose.

Regional citrate anticoagulation has become popular for CRRT in both adult and pediatric patients. Citrate, introduced into the CRRT circuit, chelates calcium, which is a required cofactor in both the intrinsic and extrinsic arms of the clotting cascade. Calcium is infused back into the patient through a central access to prevent systemic hypocalcemia. Citrate is metabolized to bicarbonate, acting as a source of base. Several protocols have been developed for regional citrate anticoagulation in CRRT.[57-60] The systems are stable and require less monitoring than heparin-based anticoagulation. Disadvantages include the potential for acid/base imbalance, the risk of hypercalcemia or hypocalcemia, citrate excess due to poor metabolism or diminished clearance, and the need for additional central access for high rates of calcium delivery.

Many critically ill patients have disorders of coagulation as a part of their multiple organ system injury and can undergo CRRT without exogenous anticoagulation. Increased clotting of the CRRT circuit in such patients may be a sign of improving clinical status. A study of pediatric CRRT suggested that circuits that are run without anticoagulation have a significantly shorter life span; thus it may be appropriate to consider the use of anticoagulation even in the coagulopathic patient to ensure continued delivery of the therapy.[61]

Patient and vascular access size can limit blood pump rate. The current generation

of CRRT machines can run at lower blood pump speeds with greater accuracy than did earlier systems.

Many brands of hemofilter are available for CRRT. Larger surface areas will permit more rapid ultrafiltration and clearance by convection. Of particular interest in the pediatric patient are reports of profound hypotensive events related to the use of a type of polyacrylonitrile hemofilter known as the acrylonitrile AN-69 membrane.[62] This reaction, occurring rapidly when the patient's blood comes in contact with the hemofilter, is thought to be related to the release of bradykinin in response to the low pH of blood used to prime the CRRT circuit. Smaller patients and those with metabolic acidosis seem to be at greatest risk. Maneuvers to adjust pH within the circuit and limit this reaction have been described.[62-64] Some practitioners prefer to avoid use of the AN-69 membrane to limit the risk of complication, while others choose to tolerate this potential complication in patients with sepsis in light of the relatively high interleukin-6 clearance provided by AN-69 membranes.[65]

Dialysate and Infused Fluids

Nearly all of the current CRRT machines use premade, fully compounded dialysate or hemofiltration fluid rather than generating dialysis fluid online from concentrates (during IHD the dialysate is generated online). Commercially available dialysis and hemofiltration fluid, compounded under quality-controlled conditions and delivered in premixed sterile bags, have largely replaced the use of extemporaneously prepared fluid from local pharmacy services. Several manufacturers offer solutions for CRRT; the products come in a variety of electrolyte concentrations to suit differing clinical needs. It has been suggested that the use of commercial CRRT solutions, rather than those made by a local pharmacy, can reduce the likelihood of errors related to solution preparation.[66]

Replacement fluids are infused to the CRRT system either before the hemofilter ("prefilter" or "predilution") or after ("postfilter" or "postdilution"). Prefilter delivery reduces convective clearance at a given ultrafiltration rate because the blood entering the hemofilter will be diluted by the replacement fluid. This reduction, however, can be easily overcome with an increase of the ultrafiltration rate. Furthermore, prefilter replacement may permit higher ultrafiltration rates because it limits hemoconcentration within the hemofilter and thus lessens the chances of filter clotting; this may be less of a concern with citrate anticoagulation, which is very effective at preserving filter life. Some CRRT machines will permit either prefilter or postfilter delivery of replacement fluids, whereas others have a fixed location for replacement fluids.

Clearance

CRRT blood pump, dialysate, and replacement fluid rates traditionally have been lower overall than those used in IHD. Consequently, clearance rates are lower but total daily clearance increases because the therapy is continuous. In most prescriptions, the limiting factor in CRRT clearance is the solution flow rate; greater rates of clearance often can be achieved with an increase in the rate of dialysate or replacement fluid. Newer CRRT machines are capable of higher solution rates than in the past. Slower blood pump speeds can also potentially limit clearances; some

newer devices are capable of higher blood pump speeds. Controversy exists in adult patients regarding appropriate goals for clearance. An influential single-center study suggested better outcomes with higher rates of clearance,[67] but this finding has not been reproduced in subsequent multicenter trials.[68,69] This question has not been fully studied in children.

Slow, steady ultrafiltration to gradually achieve fluid balance and then maintain it is the hallmark of CRRT. Slow ultrafiltration can permit movement of extravascular fluid into the vascular space at a rate roughly equal to the ultrafiltration rate, which allows greater mobilization of fluid while the risk of acute intravascular volume depletion and hypotension is limited. Ultrafiltration rates must be chosen on the basis of clinical status of the patient and fluid balance goals; frequent reevaluation is often necessary.

Disadvantages and Complications

Like IHD, CRRT requires vascular access, which can be difficult to obtain in infants and small children. Data suggest that 5-Fr single-lumen catheters should not be used for CRRT because they are associated with significantly shorter functional CRRT circuit survival.[50] Continuous extracorporeal perfusion and anticoagulation carry risks of bleeding and infection. Some patients experience blood pressure instability despite the slow method of ultrafiltration. Continuous exposure to heparin can lead to heparin-induced thrombocytopenia. Patients receiving citrate anticoagulation are at risk for acid/base disturbance or hypocalcemia. Citrate excess can cause low patient ionized calcium with normal or high total calcium levels, the so-called *calcium gap* or *citrate lock*,[58,70] which occurs when excess citrate binds free calcium in the patient. Under these circumstances, citrate delivery should be reduced or clearance through the CRRT system should be increased.

Intensive Care Unit Issues

Continuous clearance on CRRT, particularly with convective modalities, can cause profound electrolyte deficiencies. Careful attention must be paid to appropriate replacement of electrolytes lost through CRRT. Similarly, nitrogen losses on CRRT can be high.[71] Patients require increased nutritional support during CRRT therapy, and careful consideration of the nutritional prescription is required.[72] Medication dosages often require adjustment because of losses through the CRRT system. Coordination between the ICU staff and nephrology staff is essential to establish appropriate goals for fluid removal and metabolic control.

Extended Daily Dialysis

IHD sessions can be extended in length to provide therapy that approaches CRRT. Variously referred to as slow low-efficiency dialysis or slow extended daily dialysis, such techniques can provide improved molecular clearance with better tolerance of ultrafiltration when compared with conventional schedules for IHD. Sessions may run 6 to 8 hours or more on a daily basis.[73]

Some institutions may prefer extended daily dialysis methods because they obviate the need to purchase and maintain separate, dedicated CRRT equipment,

using instead standard IHD machines that have been adapted for longer session length. In addition, disposable materials for IHD are usually less expensive than are those for CRRT, potentially leading to cost savings. Because the patient is not connected to the device 24 hours a day, patient mobility for tests or surgical procedures may be facilitated and risk of treatment-related complications may be reduced. Online generation of dialysate, as for standard IHD, greatly simplifies the question of solutions compared with premixed bags that must be frequently exchanged for CRRT. However, most online dialysate is not sterile, raising a theoretic risk for the critically ill patient. Newer devices capable of extended therapies can be adapted to provide ultrapure dialysis fluid, which may mitigate this potential concern. Individual institutions may need to consider staffing requirements related to tending an IHD device for extended sessions.

Although use of extended intermittent hemodialysis (EIHD) techniques for both adult and pediatric patients is growing, the literature has a dearth of information regarding efficacy in the pediatric population. This modality is often chosen for pragmatic reasons rather than because of proven superiority. Meta-analysis of adult studies comparing EIHD and CRRT limited to randomized control trials found no differences in recovery in renal function, fluid removal, days in the intensive care unit, or mortality.[74] It remains a reasonable option under the appropriate circumstances.

Outcomes of Renal Replacement in Critically Ill Children

Outcome data comparing modalities for pediatric renal replacement are sparse. Most studies are from single centers and are limited by small numbers of subjects.

Studies in pediatric renal replacement therapy have centered on CRRT. Findings from five studies, comprising an aggregate of more than 400 patients, demonstrate an association of higher mortality for patients with more severe levels of volume overload.[6-9,75] A multicenter observational registry has provided insight on outcomes in pediatric CRRT.[55] Overall survival on CRRT in this cohort of more than 300 critically ill children was 58%; this percentage is superior to previously reported outcomes and likely represents improvement in CRRT techniques as well as overall critical care for the pediatric patient. Outcomes in the subpopulations of children with multisystem organ dysfunction and stem cell transplant who required CRRT also were noted to be improved compared with historical reports.[6,76] Because these studies did not compare CRRT to other interventions, no specific evidence-based comments can be made regarding choice of modality in the modern era, and this decision is largely based on experience and opinion.

Overall mortality of patients with AKI was determined to be 15.3% in a cross-sectional analysis of the 2009 Kids Inpatient Database comprising 2,644,263 children of whom 10,322 had developed AKI.[77] The study also demonstrated that children younger than 1 month of age, children requiring critical care, and those requiring dialysis had the highest rate of inpatient mortality.

Advances in Pediatric Renal Replacement

Therapies

Pediatric renal replacement therapy traditionally has come from adaptation of adult technologies to the smaller pediatric patient. Advancement in technology has resulted in smaller filter size, permitting lower blood flow rate and smaller extracorporeal blood volume. Despite these advancements, renal replacement therapy for smaller patients remains a challenge; some consider manual PD as the only option in patients who are less than 3 kg. Two therapies have been developed specifically for neonates and small children. The first is a CRRT machine developed in Italy by Dr. Claudio Ronco. Named CARPEDIEM (Cardio-Renal Pediatric Dialysis Emergency Machine), it has low extracorporeal blood volume of <30 mL and accurate ultrafiltration control with a precision of 1 gram. Four- and seven-French double-lumen catheters can be utilized for access. The therapy has been used successfully in patients <3 kg.[78] The second device is a hemodialysis machine developed by Dr. Malcom G. Coulthard's group in Newcastle, United Kingdom, named NIDUS (Newcastle Infant Dialysis and Ultrafiltration System). Using a syringe-based system, the machine withdraws 5- to 12.5-mL aliquots of blood from a single-lumen central venous catheter and passes it through a dialyzer filter before returning it to the patient. Extracorporeal blood volume is limited to 9.3 mL, and ultrafiltration precision is controlled to 3.2 μL.[79] Both of these devices offer the hope of providing renal replacement therapies safely to neonates and small children.

Summary

Pediatric patients who require renal replacement therapy represent a special challenge. Multiple modalities are available, and the best choice may be dictated by the clinical situation and local expertise. Careful attention to fluid and electrolyte balance and appropriate nutritional support and close interaction between critical care and nephrology personnel will yield the best outcomes.

CHAPTER 79

Acute Severe Hypertension

Joseph T. Flynn

PEARLS

- Acute severe hypertension, defined as symptomatic blood pressure elevation with evidence of acute hypertensive target organ damage, requires prompt therapy to prevent or ameliorate further target organ damage.
- The most common causes of acute severe hypertension in children are renal and cardiac conditions, and the central nervous system is the most commonly affected target organ.
- Although hypervolemia is common in many patients with acute severe hypertension, the high perfusion pressure may lead to pressure diuresis, rendering some patients relatively hypovolemic, with hemoconcentration and activation of the renin-angiotensin-aldosterone system. Consequently, persistent hypovolemia may trigger a vicious cycle of further stimulation of the renin-angiotensin-aldosterone system, thus increasing systemic vascular resistance.
- Treatment of acute severe hypertension requires continuous monitoring of blood pressure and administration of intravenous antihypertensive medication(s), most commonly labetalol or nicardipine.
- In clinical practice, mean arterial pressure during a hypertensive crisis should be lowered no more than 25% within the first 8 hours to prevent harm from dropping blood pressure and thus organ perfusion too rapidly (eg, cerebral, coronary, or renal ischemia).

Introduction

Systemic hypertension (HTN) is a major lifelong condition that begins in childhood and is one of the leading causes of premature death in both developed countries and developing nations. The current pediatric obesity epidemic along with other lifestyle choices has likely led to the increasing numbers of children now being diagnosed with HTN.[1] Current estimates suggest that up to 5% of children have HTN compared with estimates of approximately 1% in the early 2000s, and another 10% to 25% have prehypertension.[1-3] Although most hypertensive patients in the pediatric intensive care unit (PICU) will have underlying causes for their blood pressure (BP) elevation, the increasing prevalence of pediatric primary HTN may ultimately

increase the frequency with which such patients present to the PICU.

Several questions are commonly posed to the intensivist when managing a patient with acute severe HTN: What constitutes acute severe HTN in the PICU? Is this level of HTN dangerous? Does the HTN represent a transient acute response, or is there an underlying chronic process to be uncovered? Is it important to manage the high BP at this moment? How aggressively should it be managed? The objective of this chapter is to establish the foundation for understanding the deleterious effects of systemic HTN, recognizing when invasive versus noninvasive monitoring is warranted, and developing a prompt but measured approach to management.

Terminology

The most recent clinical practice guidelines for diagnosing and managing HTN in children and adolescents were published in 2004 by the National High Blood Pressure Education Program[4] and were designed to mirror adult guidelines published in the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure.[5] Using a statistical definition based on the distribution of BP values in the pediatric population, HTN in children and adolescents is defined as sustained systolic or diastolic BP elevation greater than or equal to the 95th percentile for age, gender, and height.[4] Its severity can be further classified according to the scheme in Table 79.1, which also provides the adult HTN staging criteria,[5] which should be applied to adolescents aged 18 years and older.

TABLE 79.1

Classification of Blood Pressure Levels in Children and Adolescents

Blood Pressure Classification	Children and Adolescents <18 Years of Age	Adolescents ≥18 Years of Age
Normal	SBP and DBP <90th percentile	SBP <120 mm Hg and DBP <80 mm Hg
Prehypertension	SBP or DBP 90th-95th percentile; or if BP is >120/80 even if <90th percentile	SBP 120-139 mm Hg or DBP 80-89 mm Hg
Stage 1 hypertension	SBP or DBP ≥95th to 99th percentile plus 5 mm Hg	SBP 140-159 mm Hg or DBP 90-99 mm Hg
Stage 2 hypertension	SBP or DBP >99th percentile plus 5 mm Hg	SBP ≥160 mm Hg or DBP ≥100 mm Hg

DBP, diastolic blood pressure; *SBP*, systolic blood pressure.

Adapted from National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents. The fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents. Pediatrics. 2004;114(2 suppl):555-576; and Chobanian AV, Bakris GL, Black HR, et al. The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure: the JNC 7 report. JAMA. 2003;289:2560-2572.

Severe HTN, however, has not been as rigorously defined, which has led to some confusion with respect to terminology. The clinical state of a "malignant sclerosis" or "bösartig hypertension" was first reported by Volhard and Fahr in 1914 in patients with HTN and "hypernephrosclerosis."[6] In 1928, Keith and colleagues described 81 cases of what was termed "the malignant hypertension syndrome," which was a diagnosis made before end-stage damage of retinal, cerebral, cardiac, or renal function occurred.[7,8] It was also the first description of pediatric patients with significantly uncontrolled HTN. Subsequently, the terms *hypertensive crisis* and

hypertensive emergency have appeared interchangeably in the literature, usually to denote a rapidly elevated level of either systolic or diastolic BP that is associated with end-organ damage. Organs commonly affected include the central nervous system (CNS; hypertensive encephalopathy, retinal vasculopathy-induced visual changes, cerebral infarction, and hemorrhage), the cardiovascular system (congestive heart failure, myocardial ischemia, aortic dissection), and the kidneys (proteinuria, hematuria, and acute renal insufficiency).

Traditionally, severe HTN has been divided into hypertensive emergencies and hypertensive urgencies, the former associated with life-threatening symptoms or target-organ injury and the latter associated with less significant symptoms and no target-organ injury.[9] For example, an adolescent with seizures and hypertensive encephalopathy would be considered to be experiencing a hypertensive emergency, whereas a hypertensive child with nausea and vomiting would be classified as a hypertensive urgency. This distinction is not absolute and depends somewhat on clinical judgment. Given the lack of clear distinction in terminology, the term *acute severe hypertension* will be utilized in this chapter. This can be defined as an acute BP elevation that fulfills (and usually exceeds) the definition of stage 2 HTN and that is accompanied by severe symptoms; physical exam or laboratory findings of accelerated HTN are frequently also present.[10]

Etiology

HTN may be either primary (also known as "essential") or secondary to another underlying medical condition. Children with primary HTN are frequently overweight and have positive family histories for HTN and cardiovascular disease.[11] The prevalence of HTN increases progressively with a rise in body mass index, with approximately 30% of overweight children (body mass index >95th percentile) exhibiting HTN.[12] That said, although the frequency of primary HTN has been increasing,[1] it is unusual in the PICU, with almost all cases of acute severe HTN being secondary to another condition.[10]

Secondary causes of HTN can be both transient and sustained. The most common reasons for transiently elevated BP in a critical care unit are inadequately treated pain and agitation. Without a high degree of suspicion, this can be difficult to detect, particularly if neuromuscular blockade is administered. Tachycardia as well as eye tearing with noxious interventions is a useful clue to this condition. Drug-induced HTN is also common in the critical care setting, especially when high-dose corticosteroids are used in patients with organ transplantation and other immunologic conditions. A number of other drugs associated with elevated BP are listed in Table 79.2. A review of all medications taken by the patient, as well as considering illicit drug use, is therefore indicated for all patients with an elevated BP. A patient's fluid balance should also be reviewed when HTN develops while in the ICU. Apparently innocuous discrepancies between input and output for a single day can cumulatively produce significant fluid overload after several days, although this alone is not typically enough to cause HTN in the absence of other renal, cardiovascular, or CNS problems that raise systemic vascular resistance (SVR), cardiac output (CO), or both. Finally, postoperative HTN is common in the ICU setting, occurring in up to 75% of patients. Initially, factors such as hypoxia, hypercarbia (through its sympathomimetic effects), and pain should be promptly

and adequately addressed.[13] Afterward, pharmacologic therapy is indicated if HTN is refractory or sustained despite adequate ventilation, sedation, and analgesia.

TABLE 79.2

Drug-Induced Hypertension

Drug withdrawal (narcotic, benzodiazepine)[a]
Cyclosporine and tacrolimus[a]
Erythropoietin
Glucocorticoids and mineralocorticoids
Heavy metals
Maternal drug use (cocaine, heroin)
MDMA ("Ecstasy")[a]
Nonsteroidal antiinflammatory agents
Oral contraceptive agents
Rebound after withdrawal of antihypertensives (especially clonidine, methyldopa, and β-blockers)[a]
Sympathomimetic drugs (amphetamines, cocaine, ephedrine, lysergic acid diethylamide, phenylephrine)[a]
Theophylline/caffeine

[a]More likely to present acutely.

Renal disease predominates in most pediatric case series of acute severe HTN (Table 79.3). Deal and coworkers from Great Ormond Street Hospital retrospectively reviewed their experience with severe HTN in children in 1992.[14] The most common causes of severe HTN in their series included reflux nephropathy, glomerular disease, renovascular disease, obstructive uropathy, and hemolytic-uremic syndrome, which together accounted for 76% of the cases. In a relatively large series of children with severe HTN treated with intravenous nicardipine,[15] causes included complications of organ transplantation, multiorgan failure, renovascular disease, and acute kidney injury. Renal disease accounted for 48% of patients included in a more recent case series focusing on the use of intravenous labetalol in severely hypertensive infants.[16]

TABLE 79.3

Causes of Severe Hypertension in Children and Adolescents

Renal Disease	Malignancy
Glomerulonephritis, especially membranoproliferative glomerulonephritis	Pheochromocytoma
Reflux nephropathy	Wilms tumor
Obstructive uropathy	Neuroblastoma
Acute kidney injury	
Polycystic kidney disease	
Hemolytic-uremic syndrome	
End-stage renal disease at presentation	
Vascular	**Other**
Aortic coarctation (thoracic, abdominal)	Medication noncompliance in a patient with known hypertension
Renal artery stenosis	Drug-induced (see Table 79.2)
Vasculitis	Primary hypertension (rare)

Severe fluid overload in dialysis patients, or noncompliance with antihypertensive therapy in patients with established HTN of any cause, may also result in severe, symptomatic HTN requiring immediate treatment. This was clearly demonstrated in a case series of adults presenting to the emergency department of a teaching hospital in the United States.[17] In that study, 90% of patients requiring intervention for a hypertensive urgency had a known diagnosis of HTN; the most common contributing factors to the severe BP elevation included running out of prescribed

medications and medication noncompliance. Although no similar pediatric data exist, this is likely a not infrequent situation in the young as well, particularly for hypertensive children and adolescents followed at referral centers. Finally, abrupt withdrawal of clonidine, dexmedetomidine, or a beta-adrenergic blocker may result in severe “rebound” HTN that may require prompt intervention.

Pathophysiology

The mechanisms responsible for generating and maintaining acute severe HTN crisis continue to be elucidated. What seems plausible in many cases is that there is a triggering event that precipitates a dramatic increase in BP over a short time period in a patient who is hypertensive at baseline. This event then leads to further arteriolar damage that prolongs the hypertensive state.

Mean arterial pressure (MAP) is approximately equal to the product of CO and SVR, as expressed mathematically by the following equation: $MAP \cong CO \times SVR$ (central venous pressure should be subtracted from the MAP in this equation but is usually so small it can be ignored). Thus factors that increase either CO or SVR lead to elevated BP if the other does not decrease proportionally. In addition, chronically, these factors have an interdependent interaction that is still poorly understood. For example, while the initiating event leading to HTN may cause a rise in CO, a compensatory rise in peripheral vascular resistance often develops that may persist even after CO returns to baseline.[18]

Endothelial Homeostasis

The endothelium seems to play a crucial role in the development of severe symptomatic HTN (see also Chapter 27). The endothelium is on the receiving end of the excessive pressures and shear stress generated from high blood flows along with concomitant increased resistance imparted by the vascular architectural scaffolding and surrounding smooth muscle cells. Aside from structural trauma, endothelial cell function is also affected. For instance, the stressed endothelial cell increases intracellular levels of nuclear factor-κB (NF-κB).[19] In turn, NF-κB results in expression of vascular cell adhesion molecule-1, which binds to monocytes and T lymphocytes (facilitating invasion through the vascular wall that normally does not occur) and contributes to the inflammatory state.[19,20] The proinflammatory mediators interleukin-1β and tumor necrosis factor-α also induce vascular cell adhesion molecule-1 expression in endothelial cells through the NF-κB pathway.[19] In addition to vasoconstrictor mediators, the coagulation system also has been implicated in the pathogenesis of HTN; injured endothelial cells locally activate the coagulation cascade and promote platelet aggregation that leads to a prothrombotic surface.[19,21,22]

Adults with primary HTN who experienced acute severe HTN demonstrated a significant decline in BP when given L-arginine (a precursor of nitric oxide [NO]) compared with patients who also had primary HTN but had not experienced a similar event. This observation underscores the importance of the endothelium in the pathogenesis of acute severe HTN because an intact functional endothelial cell surface is necessary to respond to L-arginine.[23] Von Willebrand factor (an endothelial cell surface marker), P-selectin (platelet activation), and fibrinogen serum levels were

all increased in hypertensive adult patients with acute severe HTN compared with control hypertensive subjects, suggesting that alterations in the homeostasis of the endothelial or the coagulation system occur during an episode of acute severe HTN.[24]

Sympathetic Nervous System Activation

A common cause of increased CO in hypertensive individuals is sympathetic nervous system (SNS) activation, often in concert with an increase in intravascular volume. At the same time, SNS activation further increases SVR, exacerbating the rise in BP. The therapeutic approach to HTN depends on reducing SVR and often suppressing or reducing SNS activation. Without the latter being suppressed, the drop in SVR mediated by a vasodilator may be compensated by an increase in sympathetic activation with a resultant increase in CO and no net reduction in BP.

The SNS can also be the cause of severe HTN. This is particularly seen in children with pheochromocytomas and other tumors that produce vasoactive substances, including neuroblastoma.[25] Hemodialysis can contribute to a substantial increase in catecholamines and also of renin, which thus can contribute to HTN.[26] Increased sympathetic activity can worsen severe HTN in several conditions, including renovascular HTN and polycystic kidney disease, and seems to be unrelated to the level of kidney function. Renal ischemia triggered by these diseases seems to cause the systemic overactivation.[27] Activation of the SNS leading to systemic vasoconstriction is generally accepted as the mechanism of severe postoperative HTN.[28]

Renin-Angiotensin-Aldosterone System

The renin-angiotensin-aldosterone system (RAAS) is thought to play a prominent role in many patients during an episode of acute severe HTN.[22,29] Renin is a proteolytic enzyme synthesized in the juxtaglomerular cells of the afferent renal arterioles that cleaves angiotensinogen (an α_2-globulin synthesized in the liver) to create angiotensin I (a decapeptide). In turn, angiotensin-converting enzyme (ACE) coverts angiotensin I to angiotensin II (an octapeptide), which acts at the angiotensin type 1 receptor (a G-coupled receptor found in renal afferent and efferent arterioles) to cause vasoconstriction, increased aldosterone release, and enhanced sodium and water reabsorption (see also Chapter 81).[18]

Increased serum renin levels can reflect a primary condition, such as renovascular disease, or be secondary to renal parenchymal ischemia, hypotension, hypovolemia, increased sympathetic effects, β-adrenergic agonists, or a combination of these factors.[18,30] Ultimately, increased renin levels raise BP through a number of mechanisms primarily mediated through angiotensin II. Aside from its vasoconstrictive properties, angiotensin II increases the expression of aldosterone that leads to increased renal sodium and water retention, thus augmenting CO by increasing intravascular volume. Angiotensin II also induces the expression of interleukin-6 and NF-κB that in turn leads to elevated levels of tumor necrosis factor-α and increases nicotinamide adenine dinucleotide phosphate oxidase activity; the latter generates reactive oxygen species, promoting oxidative stress, and inhibits the

cytokine-mediated activation of inducible-nitric oxide synthase (iNOS) that attenuates vasodilation.[18] Over time the collective result of these processes is enhanced and sustained endothelial cell trauma, vascular dysfunction, and ultimately end-organ damage.

Focal impairment of renal blood flow with release of renin and a subsequent increase in circulating angiotensin II underlie many types of childhood HTN.[31] For example, thromboemboli from umbilical or central vascular catheters may impair renal perfusion, and coarctation of the aorta is associated with high peripheral renin activity.[31,32]

Nitric Oxide

NO, now recognized as a ubiquitous biological effector, is a labile, short-lived chemical produced from arginine via NO synthases.[33] These synthases are distinguished by cellular distribution and by the requirement for calcium as a cofactor. The constitutive isoform of NOS is believed most responsible for basal vasomotor tone, although iNOS may have a role. NO is released continuously from arteries and arterioles but not from veins. In addition, other mediators function through the NO system. For instance, bradykinin stimulates the release of NO to produce vasodilation. NO diffuses from the endothelium to the vascular smooth muscle cell, where it produces its vasodilatory effect in part by increasing the intracellular concentration of cyclic guanosine monophosphate (cGMP) through stimulation of soluble guanylate cyclase. NO that diffuses from the local endothelial environment reacts with hemoglobin, forming nitrosohemoglobin and methemoglobin. Thus HTN need not be attributed only to a direct vasoconstrictor effect but also may be related to loss of basal NO vasodilation. Therapeutic agents such as sodium nitroprusside and nitroglycerin produce their systemic vasodilator action by stimulating NO production (see HTN management section that follows).

Volume Overload

An acute increase in intravascular volume is a frequent cause of acute decompensation of BP control in a patient with chronic HTN, particularly in the setting of stimuli that increase sympathetic nervous system and/or renin-angiotensin-aldosterone system activation. Volume overload is the most common mechanism leading to HTN in children with renal diseases. It is often caused by acute kidney injury with oliguria or anuria in those without preexisting renal disease.

Although volume overload is a common cause of acute severe HTN, pressure diuresis may render some patients relatively hypovolemic, producing hemoconcentration and further marked activation of the RAAS.[29] Further volume depletion may actually worsen HTN by stimulating a further increase in SVR with the potential for organ ischemia. Thus diuretics and fluid restriction are not standard therapy for patients who present with acute severe HTN; they are reserved for patients with clinically apparent fluid overload.[21,29,34]

In children on dialysis, fluid overload is probably the most important contributing factor to episodes of severe HTN. Fluid overload in dialysis patients often results

from poor adherence to dietary sodium and fluid restrictions. Chronic underdialysis and failure to consistently reach “dry weight” may lead to gradual fluid accumulation that can be clinically imperceptible until the child presents with severe HTN. This may happen even in the best dialysis center due to the difficulty in assessment of fluid status in children and also because differences in body weight may be attributed to growth instead of to fluid accumulation.[35]

Clinical Presentation

The presentation of a patient with acute severe HTN depends on underlying medical conditions, baseline systemic BP, rate of rise and degree of BP elevation, as well as effects on end organs. Headache, dizziness, and nausea/vomiting are common presenting complaints in patients with acute severe HTN, as was demonstrated in a case series of Chinese children presenting to an emergency department with acute severe HTN.[36] Visual impairment is another common presenting complaint in patients with acute severe HTN and may signal the presence of cerebral involvement.[37] A small number of severely hypertensive children may manifest isolated abdominal pain with or without vomiting.[38] Although exceedingly rare in the pediatric age group, aortic dissection may present with severe HTN along with the abrupt onset of chest or back pain.[39]

Neurologic manifestations of acute severe HTN are probably most common in children; symptoms may include seizures, lethargy, confusion, headache, and visual disturbances. Hypertensive encephalopathy (increased blood flow with pressures exceeding the autoregulatory range) typically presents as a severe headache with dizziness and changes in mental status ultimately culminating as seizures; other reported symptoms include facial palsies and visual changes that may lead to blindness and coma.[14,40,41] Hypertensive encephalopathy may occur with a mean arterial pressure below 200 mm Hg in the normotensive individual, but it may require a much higher mean arterial pressure in patients who have sustained hypertension (Fig. 79.1).

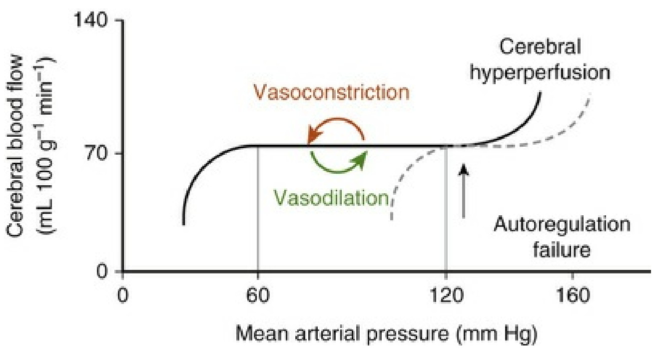

FIG. 79.1 Altered cerebral blood flow autoregulation in chronic hypertension.

Cardiac manifestations of severe acute HTN are relatively common in adults and may include asymptomatic left ventricular hypertrophy, acute congestive heart failure with pulmonary edema, and myocardial ischemia.[42,43] Unfortunately, extensive pediatric data are lacking. In two case series of children with severe HTN

from the Great Ormond Street Hospital, the incidence of left ventricular hypertrophy ranged from 13% to 66%, and the incidence of congestive heart failure was 9%.[14,44] Clearly, a high index of suspicion for an underlying cause of HTN should be maintained in a patient who presents acutely with cardiac symptoms and severe HTN, and appropriate investigation should be initiated.

Severely hypertensive children can also exhibit evidence of acute renal damage such as hematuria, albuminuria, and uremia (Fig. 79.2). However, in many cases, attempts to determine the acute renal effects of severe HTN may be complicated by the frequent association of renal parenchymal or renovascular disease with systemic HTN. Moreover, hypertensive pathology is not usually limited to a single organ like the kidney; other end-organ abnormalities usually can be seen, such as left ventricular hypertrophy and neurologic sequelae (such as mental status changes, seizures, and cerebrovascular accidents).[45] Nevertheless, children with severe HTN resulting from vasculitis have been found to have nephrotic range proteinuria, microscopic hematuria, elevated serum creatinine levels, and diminished glomerular filtration rates.[45-47]

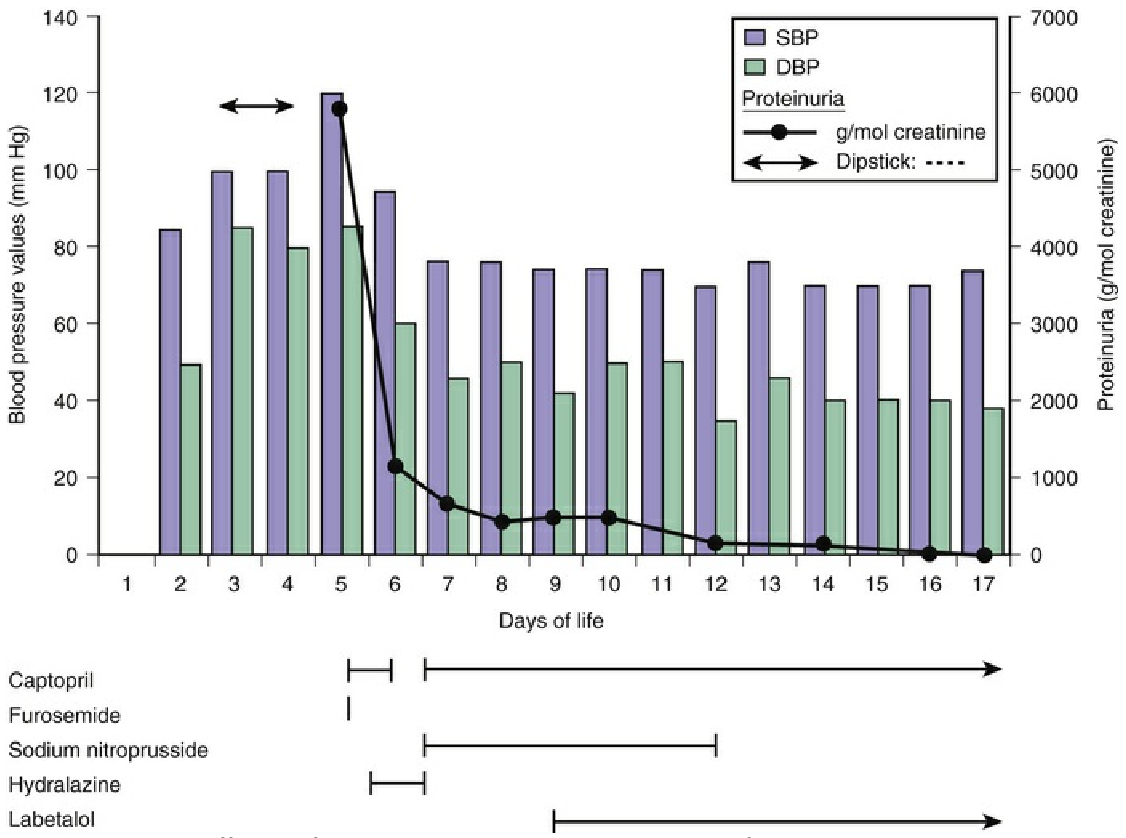

FIG. 79.2 Effects of BP control on proteinuria in an infant with renal artery stenosis. The infant also had left ventricular failure that resolved according to echocardiography performed 3 months after discharge. (Reprinted with permission from Cachat F, Bogaru A, Micheli JL, et al. Severe hypertension and massive proteinuria in a newborn with renal artery stenosis. Pediatr Nephrol. 2004;19:544-546.[126])

Patient Evaluation and Monitoring

Evaluation should be targeted at identifying both the etiology as well as any potential signs of injury to the cardiovascular, neurologic, renal, and ocular systems. A detailed history and review of systems should be obtained for all patients, with special care paid to symptoms suggestive of an underlying hypertensive disorder or target-organ damage (Table 79.4). Signs and symptoms are often reflective of the severity and rapidity of onset of HTN. Chronic HTN is more commonly asymptomatic or characterized by low-grade generalized symptoms such as fatigue and recurrent headaches. As already discussed, acutely hypertensive patients may present with a wide range of symptoms, with headache, nausea, seizures, and other neurologic complaints among the most common.

TABLE 79.4

History and Physical Examination Findings in Hypertension

Finding	Possible Significance
Historical Findings	
Complaint/Review of Systems	
Headaches, dizziness, epistaxis, visual changes	Nonspecific with respect to etiology of HTN
Abdominal/flank pain with hematuria	Renal artery or vein thrombosis
Hematuria, swelling, decreased urine output	Acute glomerulonephritis
Dysuria, frequency, urgency, nocturia, enuresis	Underlying renal disease
Joint pains/swelling, edema, rashes	Autoimmune mediated disease/glomerulonephritis
Weight loss, sweating, flushing, palpitations	Pheochromocytoma or hyperthyroidism
Muscle cramps, weakness, constipation	Hypokalemia associated with hyperaldosteronism
Delayed puberty	Congenital adrenal hyperplasia
Snoring	Sleep apnea
Prescription, over-the-counter, or illicit drug use	Drug-induced HTN
Medical History	
Umbilical artery catheterization	Renal artery thrombosis/renal embolus
Previous urinary tract infections	Renal scarring
Thyroid cancer, neurofibromatosis, von-Hippel Lindau disease	Pheochromocytoma
Family History	
HTN	Inherited forms of hypertension (AME, Gordon syndrome, Liddle syndrome, GRA), essential HTN
Renal disease	Polycystic kidney disease, Alport syndrome
Tumors	Familial pheochromocytoma, multiple endocrine neoplasia type II
Physical Examination Findings	
Vital Signs	
Tachycardia	Hyperthyroidism, pheochromocytoma, neuroblastoma, primary HTN
Bradycardia	Increased intracranial pressure (tumor, hydrocephalus)
Drop in blood pressure from upper to lower extremities	Coarctation of aorta
General	
Growth retardation	Chronic kidney disease
Truncal obesity	Cushing disease, insulin resistance
Head and Neck	
Moon facies	Cushing disease
Elfin facies	Williams syndrome
Proptosis/goiter	Hyperthyroidism
Web neck	Turner syndrome
Adenotonsillar hypertrophy	Sleep disorders
Fundal changes	Chronic or severe HTN
Cardiovascular	
Friction rub	Systemic lupus erythematosus, collagen vascular disease, uremia
Apical heave	Left ventricular hypertrophy
Disparity in pulses	Coarctation
Lungs	

Crackles/rales	Heart failure
Abdomen	
Masses	Obstructive nephropathy, Wilms tumor, neuroblastoma, pheochromocytoma, polycystic kidney disease
Hepatomegaly	Heart failure
Bruit	Renal artery stenosis, abdominal coarctation
Genitalia	
Ambiguous, viralized	Congenital adrenal hyperplasia
Extremities	
Edema	Underlying kidney disease
Joint swelling	Autoimmune disease
Rickettsial changes	Chronic kidney disease
Dermatologic	
Neurofibromas	Neurofibromatosis
Tubers, ash leaf spots, adenoma sebaceum	Tuberous sclerosis
Bronzed skin	Excessive adrenocorticotropic hormone
Acanthosis nigricans	Insulin resistance/metabolic syndrome
Striae, acne	Cushing disease
Rashes	Vasculitis/nephritis
Needle tracks	Drug-induced HTN
Neurologic	
Mental status changes	Severe HTN
Cranial nerve palsy	Severe HTN

AME, apparent mineralocorticoid excess; *GRA*, glucocorticoid-remediable aldosteronism; *HTN*, hypertension.

Physical examination should include BP measurements in all four extremities (or at least both arms and one leg) as a screening for coarctation of the aorta, which should be suspected if upper extremity pressures are higher than lower extremity pressures and lower extremity pulses are weak or absent. Special attention also should be paid to pulse rate because HTN with associated bradycardia is suggestive of increased intracranial pressure (ICP). Rapidly lowering BP in this scenario could lead to decreased cerebral perfusion and its associated sequelae. A thorough cardiac examination to identify signs of heart failure, a search for carotid or abdominal bruits, a funduscopic examination, evaluation of cutaneous lesions, and a neurologic examination also are essential in the initial evaluation of patients with severe HTN.

With respect to the funduscopic exam, evidence indicates that the pattern of retinal lesions can offer some information related to the onset of HTN. For instance, generalized arteriolar narrowing and arteriovenous nicking were associated with long-standing systemic HTN, whereas focal arteriolar narrowing, retinal hemorrhages, microaneurysms, and cotton-wool spots were indicative of recent significant increases in BP.[48] Papilledema may also be present in some patients.

As with any hypertensive child or adolescent, the remainder of the physical exam should be focused on identifying clues to underlying secondary causes of HTN such as renal disease or a genetic syndrome.[4] Specific examples can be found in Table 79.4.

Initial laboratory studies for all patients with acute severe HTN should include electrolytes, blood urea nitrogen, creatinine, complete blood cell count with peripheral smear, and urinalysis. Renal disease is the most common cause of secondary HTN in children, and both chronic and acute renal conditions may present with severe HTN. Anemia associated with chronic disease or a microangiopathic anemia resulting from disseminated activation of the coagulation system or hemolytic uremic syndrome may be seen as well. Finally, a hypokalemic metabolic alkalosis may develop with volume depletion and secondary hyperaldosteronism. Similar laboratory findings may be seen in children with

inherited monogenic forms of HTN.[49] Further laboratory evaluation for the cause of HTN should be targeted, based on the history and physical exam findings. In selected patients, thyroid studies, a drug screen, cortisol levels, and plasma or urinary catecholamines/metanephrines may help elicit the cause of elevated BP.

Renal ultrasonography is indicated for most patients to evaluate for renal parenchymal lesions such as small scarred kidneys, polycystic kidney disease, obstruction, or other structural anomalies. Doppler evaluation of blood flow to the kidneys also should be performed, although this evaluation is less sensitive than in adults at identifying subtle renal artery stenosis in smaller children and is therefore not always helpful if negative.[50] Although both computed tomography (CT) and magnetic resonance (MR) angiography have shown some promise as screening tools for renal artery stenosis, renal arteriography, sometimes in conjunction with renal vein renin sampling, remains the gold standard for identifying this lesion.[32,50,51] Further renal imaging such as a dimethylsuccinic acid (DMSA) scan may be indicated in children who are suspected of having renal scarring; plasma renin and aldosterone levels also may help discern the etiology of HTN, although typically they are not rapidly available.

A chest radiograph and electrocardiogram should be obtained at presentation to look for signs of heart failure and electrocardiographic evidence of ventricular hypertrophy, strain, or both. An echocardiogram is now recommended for all children with acute severe HTN to assess for congenital anomalies such as a coarctation of the aorta as well as for left ventricular hypertrophy and should be performed emergently if the child has signs of congestive heart failure.

A head CT scan should be done in patients with concern for increased ICP. In children with cerebral edema or increased ICP, increased BP may develop as a strategy to preserve cerebral perfusion due to the increased resistance to cerebral blood flow. Initially, a child with traumatic brain injury will often maintain sufficient cerebral blood flow over a range of BPs because of the brain's capacity for autoregulation, as depicted in Fig. 79.2.[10,21] However, if the resistance to cerebral blood flow increases, such as when ICP rises from cerebral edema, then the patient may compensate through cerebral vasodilation or increased CO to meet the metabolic needs of the brain. Cerebral vasodilation, however, will only increase ICP further. To attempt to maintain adequate cerebral blood flow, the perfusion pressure must increase as noted in the following mathematical relationship: Cerebral perfusion pressure = mean arterial pressure (MAP) − ICP. In such situations, it is prudent to undertake measures to control brain edema through hyperosmolar therapy, judicious sedation/analgesia, and avoiding maneuvers that might inadvertently increase ICP while cautiously securing the airway to control oxygenation and ventilation. Efforts to directly lower systemic BP can undermine the patient's ability to support injured but viable cerebral tissue (see also Chapter 66).

MR imaging of the brain should be considered for patients with other neurologic symptoms. The most common brain-associated finding in children with acute severe HTN has been termed “posterior reversible encephalopathy syndrome (PRES).” PRES is characterized by the sudden onset of severe HTN, headaches, altered mental status, seizures, visual loss, and even cortical blindness.[52,53] Neuroimaging studies during PRES typically demonstrate cerebral edema affecting the white matter in a parietooccipital distribution.[54] PRES is associated with immunosuppressive therapy (especially cyclosporine and tacrolimus), acute glomerulonephritis, eclampsia of

pregnancy, and hypertensive encephalopathy (Fig. 79.3).[53,55] Hypertensive emergencies and tonic-clonic seizures were presenting features in 59% of renal transplant patients who were found to have PRES on further workup.[56] In addition, nearly half of the patients with PRES had no history of uncontrolled chronic HTN. This constellation of symptoms and pathology, which has also been called reversible posterior leukoencephalopathy by other authors, typically resolves once the HTN is treated, but it may take weeks to months for the imaging abnormalities to normalize.[37,56]

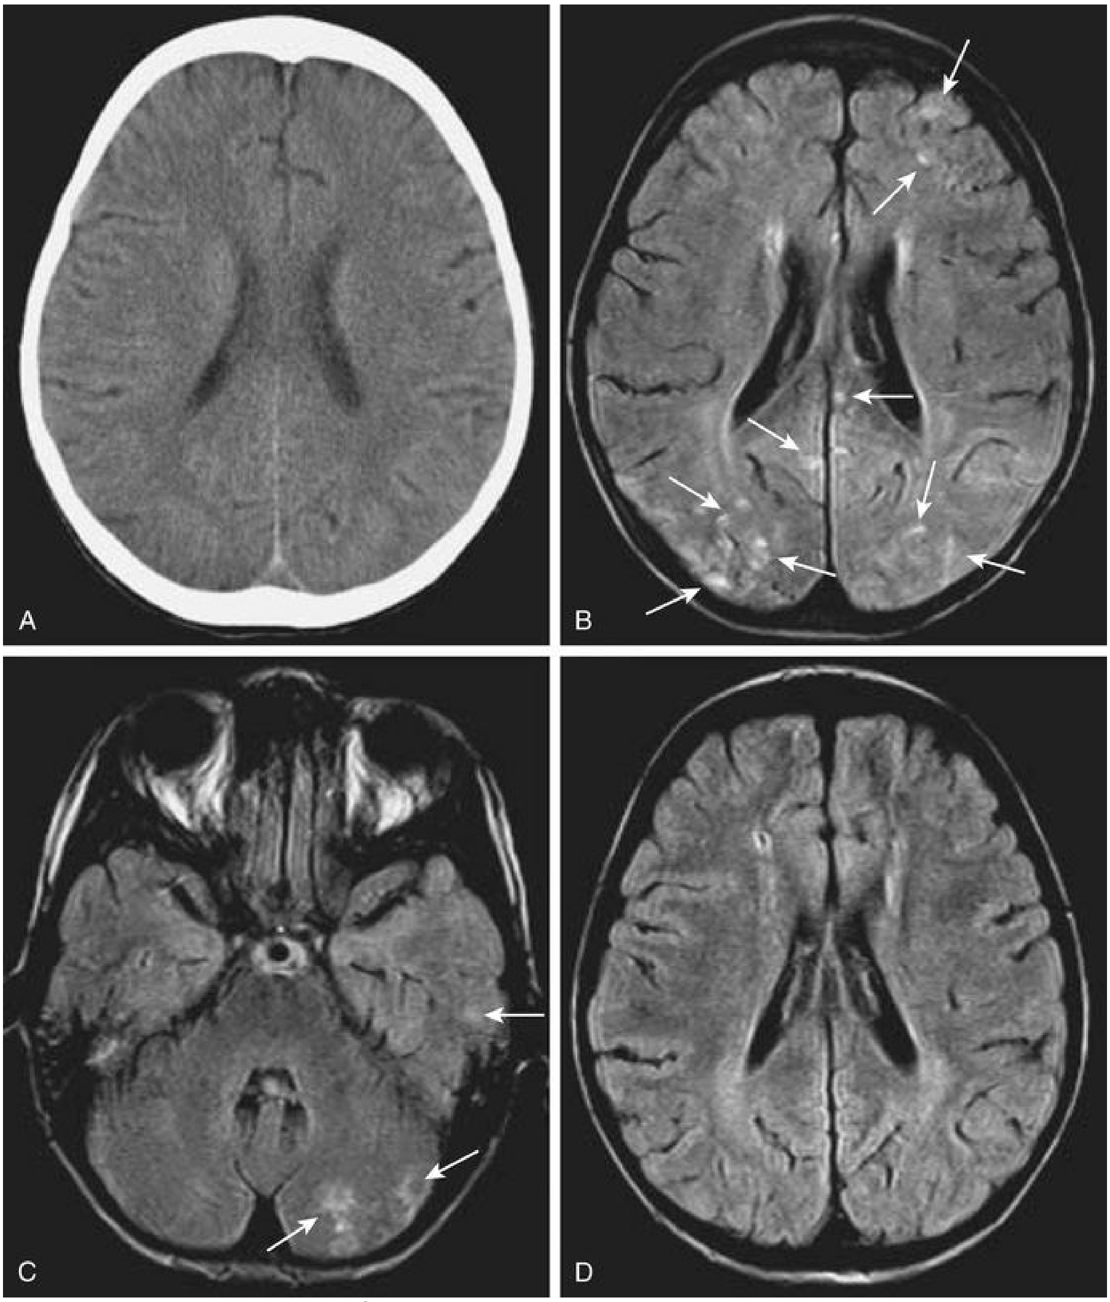

FIG. 79.3 A 6-year-old female patient with sickle cell disease, acute chest syndrome complicated with acute kidney injury, and severe hypertension. (A) Axial CT image of the brain during the episode is normal. (B, C) Axial FLAIR MR images at the same level performed the same day as the CT scan show multiple supratentorial and left cerebellar lesions *(arrows)*. (D)

Follow-up FLAIR image after the episode shows resolution of the lesions. *CT*, computed tomography; *FLAIR*, Fluid-attenuated inversion recovery; *MR*, magnetic resonance. Blood Pressure Measurement and Other Monitoring

The most critical component of identifying and monitoring patients with acute severe HTN is accurately measuring BP. Both noninvasive and invasive techniques may be used in the ICU setting and are commonly used together. The main techniques available to determine BP in the ICU are the auscultatory method, oscillometric method, Doppler method, and invasive hemodynamic monitoring.

Auscultatory, oscillometric, and Doppler BP (DBP) methods are noninvasive techniques that are based on the return of blood flow through a major artery after compression by an inflatable cuff. *Auscultatory methods* require the observer to listen to the Korotkoff sounds generated as the sphygmomanometer cuff deflates. Korotkoff sounds 1 and 5 should be used to represent systolic blood pressure (SBP) and DBP, respectively. It should be noted that the current pediatric normative BP values were generated using this technique over the brachial artery, and it is therefore the preferred site of BP measurement in children. To obtain accurate measurements, it is important that an appropriately sized cuff size be used, which should cover 80% to 100% of the upper arm circumference.[4] *Oscillometric techniques* utilize a similar technique except that the MAP is first determined from oscillometric wave forms generated as blood flow returns through the artery. SBP and DBP are then calculated using a proprietary formula specific to the brand of monitor. *Doppler devices* use changes in ultrasound frequency to infer velocity of blood flow. The Doppler shift corresponds to the turbulent flow, as signified by the Korotkoff sounds, that diminishes as laminar flow predominates.[57] As with the auscultatory method, selection of an appropriate cuff size is paramount for both the oscillometric and Doppler BP methods.

Invasive arterial lines are fluid-filled tubes attached to a pressure transducer, a device consisting of a thin flexible diaphragm connected to a strain gauge and capable of converting the pressure transmitted to an electrical signal (see Chapter 19). The most common source of inaccuracy is the influence of electrical damping on reported BP. An overdamped signal underestimates both SBP and DBP, although MAP may be accurate. On the other hand, an underdamped system overestimates SBP, especially with a hyperdynamic circulation, but does not affect MAP. This phenomenon is recognized as a narrow peaked pressure wave and wide pulse pressure. Moreover, invasive BP measured in the lower extremity is higher than in the upper extremities because of the nature of BP wave transmission, which results in an increase in SBP reading the further away from the heart it is measured.

Generally, children with acute severe HTN need to be closely monitored in a controlled setting such as the ICU, and the ideal way to continuously follow BPs is with the aid of an indwelling arterial catheter. Arterial lines can be placed in a variety of locations, but usually they are placed in peripheral arteries that supply

areas with robust collateral blood flow; common sites include the radial, dorsalis pedis, and posterior tibial arteries. Continuous intraarterial BP monitoring is generally preferred for patients with acute severe HTN because of the lability of BP when continuous infusions of intravenous (IV) medications are utilized. However, using noninvasive techniques to confirm that transduced values are accurate is a common practice because electrical damping of the transduced signal can cause inaccuracies in SBP and DBP, although MAP is likely to be less affected. Additionally, modern oscillometric devices can be programmed to take repeated measurements of BP at short intervals and may therefore sometimes be acceptable for short time periods or for patients without life-threatening symptoms.

Other important aspects of monitoring the patient with acute severe HTN include pulse oximetry and frequent neurologic assessment. Appropriate IV access should be established; ideally there should be an IV line placed that is used only for administration of antihypertensive medications. Monitoring of central venous pressure may also be helpful in selected patients, especially when volume status is otherwise difficult to assess. Finally, an indwelling Foley catheter may be needed for urine output monitoring, especially in severely hypertensive patients with known or suspected acute or chronic renal disease.

Pharmacologic Therapy

General Considerations

The therapeutic strategy for patients with acute severe HTN depends on the clinical context of the BP elevation. Hypertensive children returning from surgery need to be adequately sedated and given sufficient analgesia postoperatively for comfort and to control sympathetic activation. It is not uncommon for children to return to recovery areas, general care floors, and ICUs with variable levels of anesthetics still circulating that can permit pain, anxiety, and emergence phenomena that could be accompanied by elevated BPs. This situation by no means minimizes the potential detrimental effects of severely elevated systolic or diastolic pressures if they are inadequately treated or ignored.

It is prudent to ascertain the patient's volume status while determining the best management approach. Some clinical situations, such as the presence of pulmonary edema and renal failure, clearly identify the child with probable fluid overload. On the other hand, other children with significant HTN may exhibit a pressure-induced diuresis associated with secondary activation of the RAAS, and these patients may actually need judicious volume replenishment while managing their HTN.

The child with altered mental status, unequal (anisocoria) pupils, and systemic HTN needs agents directed at managing increased ICP such as mannitol or hypertonic saline solution, along with careful rapid sequence intubation and controlled ventilation. The goal here is to prevent cerebral herniation and not to directly lower BP too rapidly, which may be deleterious.

Finally, the strategic pharmacologic goal for a patient experiencing a hypertensive crisis is to aim for a controlled decrease in BP as opposed to a sudden rapid fall. Lowering BP to the “normal range” of MAP too rapidly may produce a clinically significant decrease in cerebral blood flow, especially in patients with preexisting chronic HTN (see Fig. 79.1). This can lead to cerebral ischemia. One group reported

the occurrence of permanent neurologic deficits in adults treated with bolus antihypertensive therapy resulting in rapid BP reduction,[58] and similar catastrophes have occurred in children as well.[59,60] Thus it is normally recommended that the BP should be reduced by 25% of the planned BP reduction over first 8 to 12 hours, a further 25% over the next 8 to 12 hours, and the final 50% over the 24 hours after that.[10]

The indications, pharmacology, and adverse effects of medications available for treatment of acute severe HTN are reviewed in the following section. Dosing for recommended agents is summarized in Table 79.5. Some agents are included in the following section but not in the table; reasons for their exclusion from the table will be evident from the discussion. Finally, a suggested algorithm for the pharmacologic management of pediatric patients with acute severe HTN can be found in Fig. 79.4.

TABLE 79.5

Recommended Antihypertensive Agents for Acute Severe Hypertension

USEFUL FOR SEVERELY HYPERTENSIVE PATIENTS WITH LIFE-THREATENING SYMPTOMS				
Drug	**Class**	**Dose**	**Route**	**Comments**
Esmolol	β-adrenergic blocker	100-500 mcg/kg/min	IV infusion	Very short-acting—constant infusion preferred. May cause profound bradycardia.
Hydralazine	Direct vasodilator	0-1-0.2 mg/kg/dose up to 0.6 mg/kg/dose	IV, IM	Should be given q4hr when given IV bolus.
Labetalol	α- and β-adrenergic blocker	Bolus: 0.20-1 mg/kg/dose, up to 40 mg/dose Infusion: 0.25-3 mg/kg/hr	IV bolus or infusion	Asthma and overt heart failure are relative contraindications.
Nicardipine	Calcium channel blocker	Bolus: 30 mcg/kg up to 2 mg/dose Infusion: 0.5-4 mcg/kg/min	IV bolus or infusion	May cause reflex tachycardia. Increases cyclosporine and tacrolimus levels. Increases cerebral blood flow.
Sodium nitroprusside	Direct vasodilator	Starting: 0-3-0.5-10 mcg/kg/min Maximum: 10 mcg/kg/min	IV infusion	Monitor cyanide levels with prolonged (>72 hr) use or in renal failure or co-administer with sodium thiosulfate. Increases cerebral blood flow.
USEFUL FOR SEVERELY HYPERTENSIVE PATIENTS WITH LESS SIGNIFICANT SYMPTOMS				
Drug	**Class**	**Dose**	**Route**	**Comments**
Clonidine	Central α_2-agonist	2-5 mcg/kg/dose, up to 10 mcg/kg/dose given q6-8hr	PO	Side effects include dry mouth and drowsiness.
Fenoldopam	Dopamine receptor agonist	0.2-0.5 mcg/kg/min up to 0.8 mcg/kg/min	IV infusion	Higher doses worsen tachycardia without further reducing BP.
Hydralazine	Direct vasodilator	0.25 mg/kg/dose up to 25 mg/dose given Q6-8 hours	PO	Half-life varies with genetically determined acetylation rates.
Isradipine	Calcium channel blocker	0.05-0.1 mg/kg/dose up to 5 mg/dose given Q6-8 hours	PO	Exaggerated fall in BP can be seen in patients receiving azole antifungals.
Minoxidil	Direct vasodilator	0.1-0.2 mg/kg/dose up to 10 mg/dose given Q8-12 hours	PO	Most potent oral vasodilator; long acting.

ACE, angiotensin-converting enzyme; *BP,* blood pressure; *IM,* intramuscular; *IV,* intravenous; *kg,* kilogram; *mcg,* microgram; *mg,* milligram; *PO,* oral.

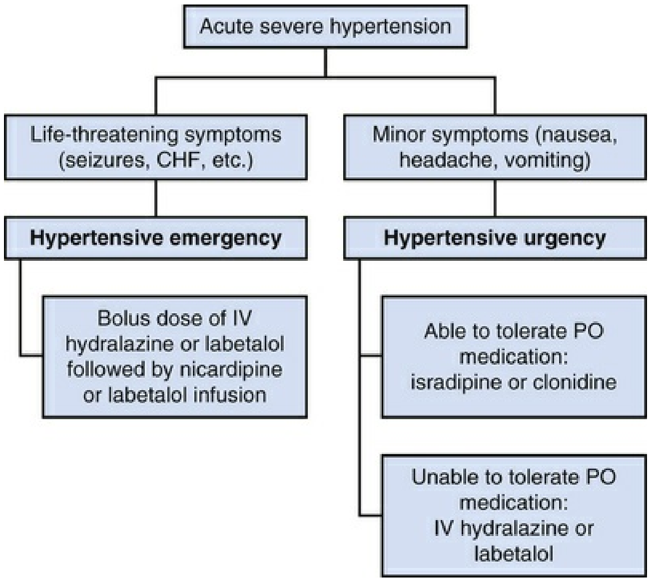

FIG. 79.4 Algorithm for initial management of children with acute severe HTN. *CHF*, congestive heart failure; *IV*, intravenous; *PO*, oral.

Clonidine

Clonidine is a centrally acting oral α2-adrenergic agonist that reduces BP by reducing cerebral sympathetic output. Clonidine is a mixed agonist that stimulates both central α_2-adrenergic and imidazoline (I_1) receptors.[61] The stimulation of α_2-adrenergic receptors in the CNS inhibits peripheral sympathetic activity that results in vasodilatation. Its effects are targeted primarily toward arterioles at lower doses.[62] Clonidine is well known as an antihypertensive agent with a favorable hemodynamic profile, especially because of the infrequency of postural hypotension. Compared to other centrally acting agents, clonidine has a relatively rapid onset of effect, approximately 15 to 30 minutes following oral administration,[63] making it attractive for use in management of acute HTN. It is metabolized hepatically into inactive forms and excreted unchanged in the urine with some gastrointestinal excretion because of enterohepatic recirculation.

Adverse effects of clonidine include bradycardia, dry mouth, and sedation.[61] In addition, severe rebound HTN may occur in patients treated chronically with clonidine (including those treated with the transdermal preparation) if the drug is abruptly stopped.

Esmolol

Esmolol is an IV pure β_1-adrenergic blocker that decreases BP by reducing CO. In a study of 17 children (6 months to 14 years), esmolol was shown to lower BP along with cardiac index, shortening fraction, and heart rate, whereas SVR remained unaffected.[64] It has a rapid onset of action and short half-life (2 to 4 minutes), which makes it ideal for critically ill patients with labile HTN who require frequent titration for BP management.[64,65] Because esmolol is rapidly hydrolyzed by esterases in the cytosol of red blood cells, its clearance is not dependent on organ blood flow or function.[66]

Like labetalol, esmolol has the advantage of not increasing ICP. It should not be used in patients with obstructive lung disease, such as asthma, and should be used with caution if the patient has congestive heart failure. It can cause profound bradycardia. In addition, the use of β-blockers alone should be avoided in children with suspected neuroendocrine catecholamine secreting tumors because the stimulation of α-receptors from these catecholamines without opposing β-stimulation can severely worsen BP.

A large multicenter, double-blind, randomized, dose-ranging study of 116 pediatric patients (younger than 6 years) with postoperative HTN after coarctation of the aorta repair studied one of three doses of esmolol (125, 250, or 500 μg/kg/min, after respective loading doses of 125, 250, and 500 μg/kg). The results showed a decrease in systolic BP in all three dose groups, but there was no statistically significant difference between groups in either the change from baseline or percentage change from baseline.[67] Despite the lack of dose response in the clinical trial setting, it is likely that esmolol can be effectively titrated to achieve control of BP in children with severe HTN. Esmolol has been used successfully for the intraoperative management of HTN during pheochromocytoma resection in children.[68] Other published experience with esmolol therapy in children without cardiovascular lesions is limited.

Hydralazine

Hydralazine, available in both IV and oral preparations, is a direct vasodilator of arteriolar smooth muscle with an unclear mechanism of action, most likely an alteration of intracellular calcium metabolism, leading to interference with the calcium movements within the vascular smooth muscle that are responsible for initiating or maintaining the contractile state. It does not affect coronary arteries or venous smooth muscle, but its effects on arteriolar smooth muscle stimulate the sympathetic nervous system, leading to tachycardia, increased renin activity, and sodium retention.[69] The positive inotropic effects of hydralazine exhibit both cyclic adenylate monophosphate–dependent and independent mechanisms, yet the importance of each remains elusive.[70] Nevertheless, it is known that intracellular calcium homeostasis is altered when hydralazine mediates its effects.[71]

Hydralazine, when given orally, has low systemic bioavailability (16% in fast acetylators and 35% in slow acetylators). Consequently, the dose needed to achieve therapeutic levels is higher in fast acetylators because the acetylated form is inactive. *N*-acetylation of hydralazine occurs in the bowel or the liver. The half-life is a function of genetically determined acetylation rates, but on average it is approximately 60 minutes; it is cleared hepatically, and elimination is a function of hepatic blood flow. The onset of action after IV administration is 5 to 20 minutes, with a duration of 1 to 4 hours. Although hydralazine's half-life is variable, its effect on BP generally persists for 2 to 4 hours.[72,73] When administered orally, hydralazine has an onset of action of 30 minutes to 2 hours and an unpredictable duration of action of 6 to 12 hours. Hydralazine also may be given intramuscularly; dosing is similar to IV administration.

Despite its long history of use in children,[74] no prospective pediatric clinical trial of hydralazine has been conducted. However, two retrospective case series of hydralazine use in hospitalized children with acute HTN suggest that this agent can

produce effective BP reduction after IV administration and that adverse effects are relatively infrequent.[75,76] However, the BP response to IV hydralazine was erratic in both reports, likely reflecting the retrospective study designs. There are no published pediatric data on the efficacy of oral hydralazine.

Adverse effects are related to the reflexive increase in sympathetic activity and include tachycardia, palpitations, flushing, headache, and dizziness. Additionally, there appears to be an increased risk of excessive BP reduction following IV hydralazine administration in children[76]; thus caution is advised when using this agent.

Isradipine

Isradipine is an oral second-generation dihydropyridine calcium channel blocker (CCB) that is specific for the L-type calcium channel found in smooth muscle. It lowers BP by relaxing arteriolar smooth muscle, leading to decreases in peripheral vascular resistance. As a result, the CCBs elicit a sympathetic discharge that causes stimulation of the sinoatrial node and consequent tachycardia.[77] It has a relatively rapid onset of action, with a peak effect that can last as long as 3 hours.

Several retrospective case series of pediatric isradipine use have established its utility for both acute and chronic HTN.[78-81] In a study of 282 hospitalized children with acute HTN treated with oral isradipine, BP reductions of 16.3 ± 11.6% (mean ±SD) for systolic BP and 24.2 ± 17.2% for diastolic BP were observed.[81] Another study examined isradipine use in 80 children with secondary HTN over a 5-year period and found that isradipine monotherapy decreased SBP by a mean of 13 mm Hg and DBP by 10 mm Hg over a broad range of ages from 1 week to 16.8 years.[79] Similar responses to isradipine (a decrease in systolic pressure of 11.8% and diastolic pressure of 17.4%) were seen retrospectively in 53 children (ages 1 day to 16 years) treated with an average dose of 0.4 mg/kg/day.[80]

Isradipine undergoes extensive first-pass metabolism in the liver by the cytochrome 4-50 isoenzyme CYP3A4.[77] It is highly protein bound and is excreted essentially as inactive metabolites in the urine (two-thirds) and feces (one-third). Adverse events attributed to isradipine occurred in 9.5% of patients in one case series and included headache, dizziness, flushing, and tachycardia.[79] Of note, an exaggerated BP response to isradipine has been observed in patients receiving concomitant treatment with azole antifungal agents,[81] so caution is advised when using isradipine in such patients.

Labetalol

Labetalol is a combined α- and β-adrenergic blocker that can be administered as a continuous IV infusion or as an IV bolus. It lowers systemic vascular resistance with minimal effect on CO.[82] It provides nonselective β-adrenergic blockade, which reduces reflex tachycardia and increased cardiac contractility that may be seen with vasodilators. β_2-adrenergic blockade would increase SVR, but this effect is counterbalanced by its α-adrenergic blockade, which is selective for the α_1-receptor, resulting in vasodilation. The α-to-β blocking ratio of the oral preparation is 1 : 3, whereas it is 1 : 7 for the IV form. Labetalol is therefore most useful in situations where HTN is produced by excessive SNS activity. Labetalol has an onset of action

of 2 to 5 minutes with a peak at 5 to 15 minutes, and it can last up to 4 hours, a longer duration of action than nitroprusside or nicardipine, and does not increase heart rate or CO as does nitroprusside.[83] It is metabolized in the liver through glucuronide conjugation and excreted in the urine, bile, and stool.

Published experience with IV labetalol in severely hypertensive children is limited to several small case series.[14,16,84] In all of these reports, labetalol was felt to be an effective antihypertensive agent; in the most recent report, labetalol was felt to have a similar antihypertensive effect as nicardipine and sodium nitroprusside. Adverse effects include bradycardia and bronchospasm, although in one report a pediatric patient with a history of asthma experienced no respiratory difficulty when given labetalol for HTN.[83] Unfortunately, no prospective pediatric trial of labetalol has been conducted.

Nicardipine

Nicardipine is an intravenous dihydropyridine CCB that is specific for L-type calcium channels and is primarily an arteriolar vasodilator. It is selective for L-type calcium channels in vascular smooth muscle as opposed to cardiac myocytes. Moreover, nicardipine has profound coronary and cerebral vasodilatory activity.[77] Its potent BP actions are without negative inotropic effects or suppression of cardiac conduction; it has minimal effects on automaticity and causes no appreciable venodilation.[77]

Many pediatric case series of IV nicardipine use in infants and children with severe HTN have been published[15,85-88]; and in all of these studies, it has been reported to be effective and well tolerated. The vasodilatory effects appear to be greater in patients with HTN than in patients with normal BP.[89] In addition, it has gained a role in various cardiovascular, neurosurgical, and general surgery procedures as well as in the postoperative period.[90]

In head-to-head trials for treatment of severe HTN in adults, nicardipine was as effective as nitroprusside.[13] Unlike nitroprusside, nicardipine does not pose the risk for cyanide or thiocyanate toxicity and can be used for a longer duration than nitroprusside. It does have a slightly longer onset of action and a much longer elimination half-life compared with nitroprusside.[89] Plasma levels of nicardipine increase rapidly in the first few hours of a continuous infusion but then reach a steady state thereafter. The elimination half-life is a few hours with normal renal function and prolonged with decreased clearance during renal failure. Given its metabolism by the hepatic P-450 enzyme system, there is the potential for clinically significant drug interactions[77]; the most important of these include decreased clearance of cyclosporine, tacrolimus, and vecuronium.

Because nicardipine may cause thrombophlebitis when given through a peripheral intravenous line, central venous administration is recommended. Like other arterial vasodilators, nicardipine has the potential to increase ICP, although another dihydropyridine CCB (nimodipine) is neuroprotective and is often used in patients with subarachnoid hemorrhage. Conversion of nicardipine infusions to oral dosing has been reported in adults,[91] but no similar reports have been published for children.

Sodium Nitroprusside

Sodium nitroprusside (SNP) lowers systemic BP both as an arteriolar (peripheral resistance vessel) and venous (peripheral capacitance vessel) dilator. Consequently, this effect often results in a reflex tachycardia because of the fall in arteriolar BP. SNP lowers right atrial pressures through relaxation of venous capacitance vessels, thus increasing venous compliance. In addition, SNP reduces right ventricular afterload through its pulmonary arterial vasodilator activity.[92] Its potent pulmonary vasodilation inhibits hypoxic-mediated pulmonary vasoconstriction.[93] Generally, when used in acutely hypertensive patients with normal left ventricular function, SNP reduces CO through its venous pooling (eg, increased venous capacitance) effects. On the other hand, SNP improves CO in patients with poor left ventricular function and diastolic ventricular distention mainly by decreasing afterload by means of relaxing arteriolar resistance vessels.[94]

SNP has a prompt onset of action and a very short half-life, making it ideal for frequent titration. It is an unstable compound that breaks down under alkaline conditions and when exposed to ambient light. Immediately during infusion, SNP interacts with oxyhemoglobin to yield methemoglobin, cyanide, and NO. In contrast to the organic nitrates (eg, nitroglycerin) that require thiol-containing compounds to generate NO, SNP spontaneously generates NO, thus functioning as a prodrug.[95] Once generated, NO activates the enzyme guanylate cyclase found within vascular smooth muscle, resulting in increased levels of cGMP, which inhibits calcium entry into vascular smooth muscle cells, producing vasodilation. Its onset of action is 30 seconds, it peaks at 2 minutes, and it is eliminated 3 minutes after cessation.

The cyanide that is produced is rapidly cleared by nonenzymatic means by reacting with sulfhydryl groups on proteins in surrounding tissue and in erythrocytes.[93] In addition, the liver enzymatically metabolizes cyanide to thiocyanate by means of rhodanese. Because the liver is the major source of rhodanese, in patients with liver failure, signs and symptoms of cyanide intoxication may develop upon nitroprusside administration. Adverse effects from methemoglobinemia generated by SNP metabolism are rare, even in patients with a congenital inability to convert methemoglobin to hemoglobin (ie, methemoglobin reductase deficiency). In any event, any patient receiving SNP in whom CNS dysfunction, cardiovascular instability, or increasing metabolic acidosis develops should be evaluated for cyanide toxicity.[93] If cyanide toxicity is suspected, SNP infusion should be stopped and therapies directed toward cyanide toxicity should be considered. Because the rate-limiting step of cyanide detoxification to thiocyanate usually entails the need for a sulfur donor, co-administration of sodium thiosulfate as a sulfur donor increases the rate of reaction of rhodanese, removing cyanide from the circulation.[89] A solution of 0.1% sodium nitroprusside and 1% sodium thiosulfate or a 1 : 10 ratio by weight in light-protected tubing is administered according to the usual dosing guidelines for sodium nitroprusside.[96-97] Alternatively, hydroxocobalamin (vitamin B_{12a}) can be used to trap the cyanide ion by exchanging the hydroxyl group for cyanide and forming cyanocobalamin, which is excreted unchanged in the urine.[98] Cyanocobalamin is the synthetic form of vitamin B_{12} (cobalamin) that is used for food additives and is nontoxic. Of note, IV methylene blue is contraindicated in treating methemoglobinemia attributable to cyanide toxicity because the conversion of methemoglobin to hemoglobin may liberate large amounts of cyanide.[98]

Thiocyanate is eliminated in the urine with an elimination half-life of 3 days in

patients with normal renal function. Because thiocyanate accumulates in patients with renal failure and can result in renal toxicity, nitroprusside should usually be avoided in children with renal failure. In fact, a significant proportion of children with normal renal function treated with SNP may develop elevated cyanide levels,[99] so widespread use of SNP in pediatric patients is probably not advisable. Clinically, patients with thiocyanate toxicity exhibit anorexia, nausea, fatigue, disorientation, and psychosis. Thiocyanate also inhibits iodine uptake by the thyroid and may produce hypothyroidism. Thus thiocyanate levels should be monitored with prolonged infusion (>24 hours).

In one study evaluating the effectiveness of nitroprusside in children presenting with acute severe HTN of renal origin, target levels of BP were achieved within 1 to 20 minutes in all patients. In addition, symptoms of cardiac failure resolved in all patients, and neurologic symptoms abated in 80% of children within 24 to 48 hours.[100] In a clinical trial in children requiring prolonged hypotension, SNP was significantly more effective than placebo in maintaining BP control.[99] The disadvantages of SNP include not only the potential for cyanide and thiocyanate toxicity but also acute hypotension, rebound HTN, increasing cerebral blood flow/ICP, oxygen desaturations (via inhibition of hypoxic vasoconstriction), and, in time, tachyphylaxis.[22]

Other Available Agents

Clevidipine is an ultra–short-acting IV dihydropyridine CCB with high specificity for vascular smooth muscle. Unlike oral dihydropyridine CCBs such as amlodipine that have long durations of action, clevidipine administration lowers BP within 2 minutes after initiation of a continuous infusion and has a rapid offset once the infusion is discontinued, with a half-life of just a few minutes.[101] This makes its pharmacokinetics similar to those of SNP; indeed, comparative studies of clevidipine and SNP in adults following coronary artery bypass have confirmed similar clinical efficacy of these two agents.[102] Clevidipine may be superior to both SNP and IV nicardipine due to its decreased tendency to produce tachycardia compared to nitroprusside and its more rapid offset of action compared to nicardipine.

Although originally developed for control of BP during surgical procedures, clevidipine has also found a role in the management of postoperative severe HTN in adults following cardiac surgery.[103] Pediatric use of clevidipine has been reported in several clinical situations, primarily in patients requiring intraoperative BP reduction.[104] In an open-label trial, clevidipine was administered to 30 children undergoing spinal fusion in whom controlled hypotension was needed. All patients achieved the desired reduction in MAP without significant adverse effects such as tachycardia.[105]

Enalaprilat is an IV form of the angiotensin-converting enzyme (ACE) inhibitor enalapril. ACE inhibition blocks the conversion of angiotensin I to angiotensin II, a potent vasoconstrictor. Thus ACE inhibition leads to vasodilation because of decreased levels of angiotensin II.[18] Interestingly, ACE also metabolizes bradykinin; hence bradykinins increase during ACE inhibition, and this effect may contribute to vasodilation as well.[106] In any event, ACE inhibitors decrease SVR and thus afterload and systolic wall stress. Consequently, CO and stroke volume improve.

All ACE inhibitors are cleared predominantly by the kidneys. Therefore doses of

these agents need to be reduced in patients with renal insufficiency. ACE inhibitors are most potent in patients with high renin levels; significant decreases in BP can occur in this population. Enalaprilat should not be used in patients with myocardial infarction, bilateral renal artery stenosis, pregnancy, or preeclampsia/eclampsia.

There is no established pediatric dose for enalaprilat. A dose range of 5 to 10 μg/kg/dose IV every 8 to 24 hours was reported as effective in one small case series of hypertensive neonates[107]; however, no further pediatric reports of this agent have been published and it is therefore probably best avoided in severely hypertensive children, many of whom will have renovascular forms of HTN, where use of an ACE inhibitor is not recommended in the acute setting.[10]

Fenoldopam is the first available peripheral dopamine$_1$ receptor (DA1) agonist, the newest class of antihypertensive agents available to treat acute severe HTN. Stimulation of the DA1 receptor causes vasodilation of peripheral arteries as well as the mesenteric and renal vasculature, with less effect in the cerebral and coronary circulations. Thus it lowers BP and peripheral vascular resistance while maintaining renal blood flow.[108] DA1 receptor stimulation leads to vasodilatation by increasing cyclic AMP (cAMP), which promotes smooth muscle relaxation. cAMP also inhibits the sodium-hydrogen exchanger and the sodium/potassium-adenosine triphosphatase pump in the renal tubule.[18] This feature gives fenoldopam the advantage of maintaining or increasing renal perfusion; its use is associated with short-term increases in urine output, sodium excretion, and creatinine clearance.

Fenoldopam has an onset and duration of action similar to that of IV nicardipine[109] and has a half-life ranging from 5 to 10 minutes.[108] It has been shown to be generally equivalent to SNP in the management of acute severe HTN in adults.[110] Pediatric experience with this agent for severe HTN is limited to a few case reports.[111,112] However, it has found use in children requiring perioperative BP control. In a blinded, randomized, prospective study of children ranging from 3 weeks to 12 years of age who were scheduled for surgery with a planned induction of hypotension, fenoldopam rapidly lowered MAP compared with placebo.[109] A retrospective analysis of 13 patients aged 4 months to 18 years with primarily cardiac lesions demonstrated increased urine output with fenoldopam without the need to increase fluid intake; no increase in serum creatinine levels or adverse hemodynamic effects were observed.[113]

Like other drugs that act through adrenergic receptor stimulation, tolerance develops in patients who take fenoldopam for longer than 48 hours. Fenoldopam has the potential to increase intraocular pressure and is known to cause a dose-dependent tachycardia.[108,109]

Minoxidil is a direct vasodilator that opens potassium channels in smooth muscle cells, causing potassium efflux, which in turn leads to hyperpolarization and relaxation.[114] It acts primarily on arterioles and does not produce venous dilatation. Minoxidil generally acts within 1 hour and its effects may last as long as 8 to 12 hours. It is renally excreted and easily removed by dialysis; therefore dose adjustment may be needed in patients with severe renal insufficiency, and it should be dosed after dialysis.[114]

Minoxidil has been shown to be effective in children with severe chronic HTN refractory to other oral agents[115] and also in children with chronic HTN experiencing acute BP elevations.[116] It has well-known side effects of hirsutism and fluid retention that are primarily seen with chronic use, so these should not be a significant

consideration in the acutely hypertensive patient.

Nitroglycerin is principally a venodilator, although arteriolar dilation occurs at higher doses. Once nitroglycerin is converted to NO, it activates guanylate cyclase within smooth muscle (similar to SNP) and stimulates the production of cGMP. The result is increased venous capacitance with a predictable decrease in myocardial preload.[117] In volume-depleted patients, reduction of myocardial preload reduces CO and is undesirable, especially in patients with compromised myocardial, cerebral, or renal perfusion.[118]

Onset of action of IV nitroglycerin is 1 to 2 minutes, with a duration of action of 3 to 5 minutes.[119] Common adverse effects include headache, orthostatic hypotension, nausea, palpitations, and flushing. The hemodynamic effects of nitroglycerin may be deleterious in patients with anatomically restrictive cardiac lesions such as aortic stenosis or other left-sided obstructive cardiac lesions. Furthermore, nitroglycerin should be avoided in patients with increased ICP because of its cerebral vasodilatory properties.

Special Situations

Preeclampsia

Pregnancy associated with preeclampsia also must be considered in female adolescents experiencing acute severe HTN. Preeclampsia is a state of hypertensive proteinuria in a pregnant woman who is at greater than 20 weeks gestation.[120] Clinically, the classic triad of preeclampsia consists of HTN, proteinuria, and edema, although now it is accepted that edema should no longer be considered a prerequisite for making the diagnosis of preeclampsia. Under these circumstances, an elevated BP separated by a minimum of 4 hours (maximum 7 days) is considered adequate for making a diagnosis for HTN (>140/90 mm Hg) or severe HTN (>160/100 mm Hg). Proteinuria is considered significant when two random urine samples collected at least 4 hours (but <7 days) apart have a level of 30 mg/dL or higher (1+) or 300 mg or more of protein are present in a 24-hour urine collection.[120] In the absence of proteinuria, pregnancy-induced HTN, gestational HTN, or chronic HTN must be considered.

The goal of managing preeclampsia is to meticulously control the BP in order to protect the fetus from insufficient placental-uterine blood flow via overly aggressive antihypertensive therapy and to avoid development of eclampsia (the condition characterized by tonic-clonic seizure activity culminating in coma). IV antihypertensives that are commonly used for acute severe HTN in pregnancy include labetalol and hydralazine, but other drugs, including esmolol and nicardipine, have been safely used.[121]

Pheochromocytoma

Although rare as a cause of HTN in childhood,[122] pheochromocytomas present a unique set of management challenges to the intensivist. Many children with pheochromocytomas initially present with severe, symptomatic HTN of unknown etiology.[123] Such children require careful immediate stabilization and gradual BP reduction as described in the preceding sections until such time as the necessary

studies can be obtained to establish the diagnosis. Although theoretically the α- and β-adrenergic blocker labetalol may seem uniquely well suited for treatment of HTN caused by a pheochromocytoma, in practice a continuous infusion of any of the intravenous antihypertensives listed in Table 79.5 could be utilized for initial BP management. Phentolamine has also been advocated in such patients,[124] although pediatric experience with this agent is extremely limited.

Once the diagnosis of pheochromocytoma has been made, the child's blood pressure should be stabilized with oral antihypertensives until the tumor can be surgically removed. Phenoxybenzamine, a potent α-adrenergic blocker, is usually recommended as the primary agent for this phase of management, although there has been a recent trend toward use of doxazosin for α blockade.[125] β-adrenergic blockade is frequently advocated as adjunctive therapy to counter tachycardia in patients treated with phenoxybenzamine. In the ICU setting, it is likely that these oral agents will need to be overlapped with IV therapy, followed by gradual discontinuation of IV therapy. Goal BP does not need to be reached prior to patient transfer out of the ICU, but the BP should be sufficiently controlled so that the patient is no longer experiencing symptoms of severe HTN.

The patient with pheochromocytoma may present back to the ICU following surgical removal of the tumor, usually for a brief period to ensure that the BP has stabilized. Intraoperatively, BP surges and arrhythmias may occur due to manipulation of the tumor. These complications are typically treated with use of rapidly acting intravenous antihypertensive agents and beta-adrenergic blockade. Volume resuscitation may be required immediately following removal of the tumor, but postoperative volume overload is not a significant concern.

Summary

Severe HTN is a potential medical emergency that needs to be addressed immediately. After a brief evaluation of the possible etiology, antihypertensive treatment should be initiated. This is mostly done with intravenous agents, of which a number of options, albeit many not well studied in children, exist. The intensivist needs a heightened awareness for factors that predispose children to severe hypertensive events as well as an understanding of the clinical symptoms that may reflect end-organ damage from critically high BPs.

SECTION VI

Metabolism, Endocrinology, and Nutrition

OUTLINE

CHAPTER 80

Cellular Respiration

Scott L. Weiss, Clifford S. Deutschman, Lance B. Becker

"In every one of us there is a living process of combustion going on very similar to that of a candle, and I must try to make that plain to you. For it is not merely true in a poetical sense."

Michael Faraday, A Course of Six Lectures on the Chemical History of a Candle (1861)

PEARLS

- Cellular respiration is largely coordinated in the mitochondria and normally aligns energy demand with energy production. In critical illness, disruption of cellular bioenergetic homeostasis may be a final common pathway for organ dysfunction and death.
- Cellular respiration consists of three related series of biochemical reactions:
- Glycolysis of carbohydrates, β-oxidation of fatty acids, and catabolism of amino acids to produce acetyl-coenzyme A (acetyl-CoA)
- Metabolism of acetyl-CoA in the Krebs cycle to produce electron-rich nicotinamide dinucleotide (NADH) and flavin adenine dinucleotide ($FADH_2$)
- Shuttling of electrons from NADH and $FADH_2$ to oxygen in order to synthesize adenosine triphosphate (ATP) in the mitochondria
- Shock is an imbalance balance between oxygen (and substrate) delivery and oxygen (and substrate) utilization such that cellular metabolic demands are not met. If oxygen delivery is not rapidly restored, ATP turnover will decrease and an altered state of bioenergetic homeostasis will lead to cell injury and organ dysfunction. Persistent mitochondrial dysfunction may contribute to a clinical state of *cytopathic hypoxia* in which cellular respiration remains abnormal even despite restoration of oxygen delivery.
- Bedside measures of cellular respiration remain challenging. The two most commonly used measures, lactate and venous oxygen saturation, provide

important information about global oxygen utilization and have proved useful to guide acute resuscitation, but they have important limitations. More direct measures of cellular respiration may be available in the near future.

- A therapeutic approach that better aligns oxygen (and substrate) utilization with oxygen (and substrate) delivery may help to restore bioenergetic homeostasis and improve cellular—and thus organ—function. Several existing and novel therapies may help to improve mitochondrial function in particular.

In 1920 Haldane was credited with the observation that hypoxemia not only stops the (respiration) machine but wrecks the (respiration) machinery as well.[1] Indeed, the priorities of pediatric advanced life support and cardiopulmonary resuscitation are to restore oxygen and substrate delivery to tissues and cells. Critical care extends these basic principles of restoration of oxygen and substrate delivery to also support oxygen utilization and cellular respiration with the goal to reestablish and maintain bioenergetic homeostasis.

Although early resuscitation targeted toward prespecified hemodynamic end points improves outcomes in children with critical illness, this strategy does not benefit all patients at all time points in disease. Alterations in cellular respiration can contribute to a bioenergetic imbalance that results in cell—and ultimately—organ dysfunction.[2] Oxygen availability and utilization are vital for cells to efficiently convert the chemical energy of nutrient molecules into useful energy in the form of adenosine triphosphate (ATP).[3] This process involves a highly regulated network of multienzyme reactions, largely coordinated in the mitochondria, which normally closely align energy demand with energy production. In critical illness, this delicate homeostatic balance may be disrupted and has been identified as a possible final common pathway for organ failure and death.[4,5] Consequently, a working knowledge of cellular respiration is a key tenet of critical care medicine.

This chapter reviews (1) major pathways of cellular respiration with a focus on the mitochondria, (2) the role of impaired cellular respiration in critical illness, particularly in shock and multiple organ dysfunction syndrome (MODS), (3) clinical assessment of oxygen utilization, and (4) potential therapeutic strategies to improve mitochondrial respiration and restore bioenergetic homeostasis.

Pathways of Cellular Respiration

Plants harness the sun's energy to split water into hydrogen and oxygen (Fig. 80.1). The hydrogen is then attached to carbon to create glucose and starch, while the oxygen is released into the atmosphere. Animals, including humans, eat plants to acquire carbohydrates (as well as other animals to obtain protein and fat), ultimately removing the hydrogen and combining it with oxygen to regenerate water. Through this cyclical process, humans convert energy in the form of photons from the sun to usable cellular energy in the form of ATP (Fig. 80.2) through a process called *oxidative phosphorylation*.[6] As will be discussed, an interconnected and alternative pathway of *anaerobic respiration* also exists within the cytoplasm, but in the absence of oxygen it is not sufficient to sustain human life.[7]

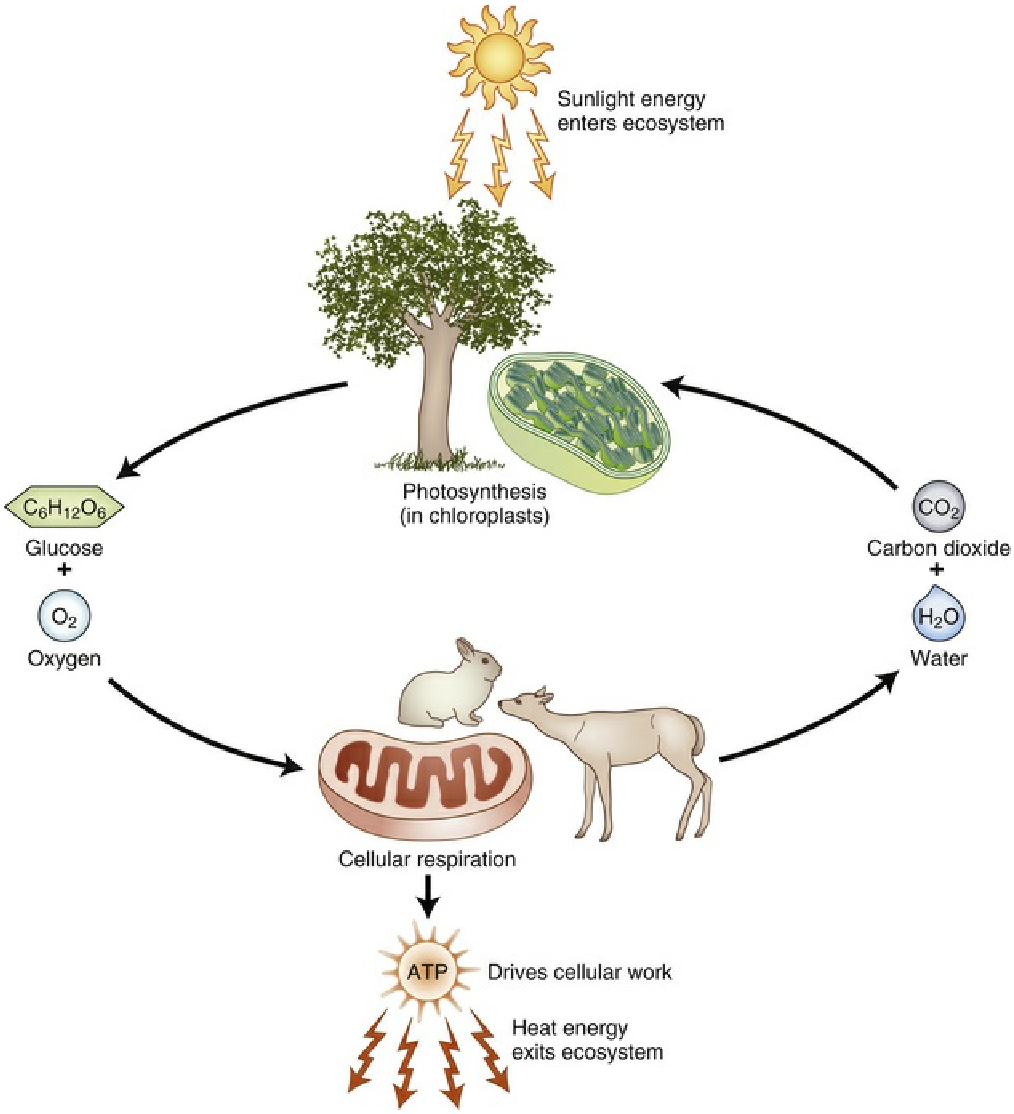

FIG. 80.1 Cyclical process through which plants help animals to convert the sun's energy into usable cellular energy in the form of ATP.

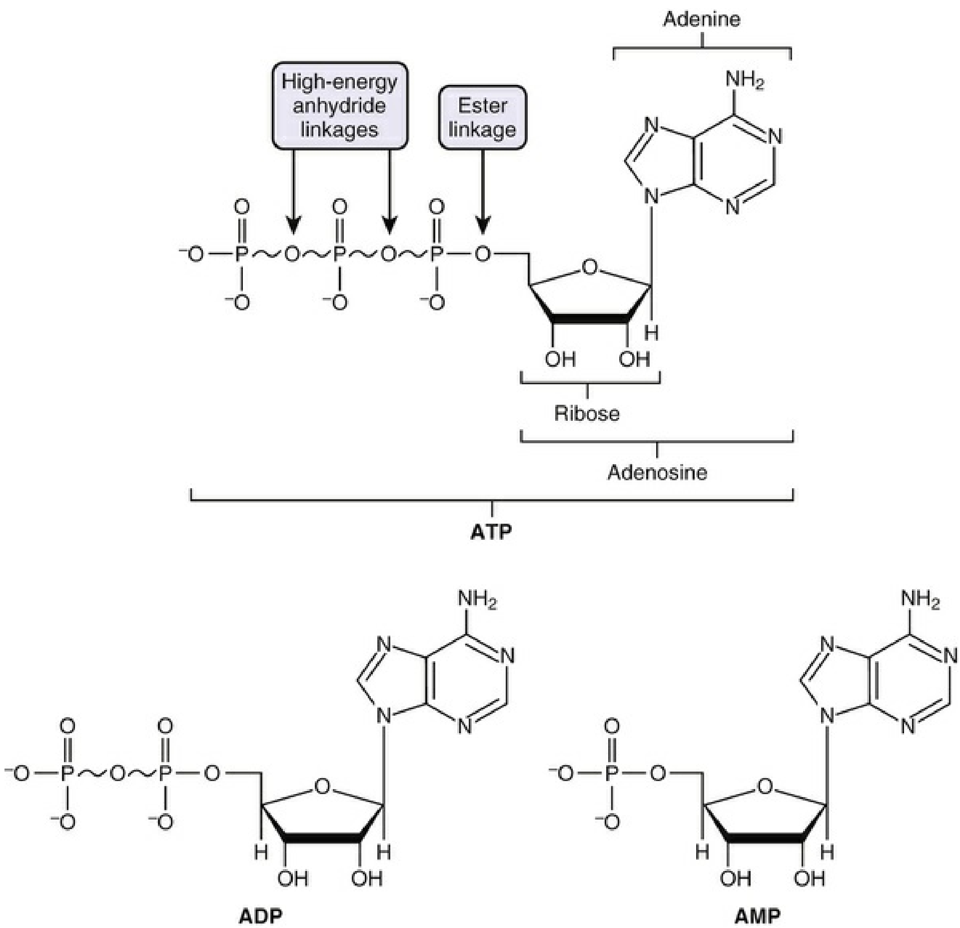

FIG. 80.2 Structure of ATP. (Modified from Baynes JW, Dominiczak MH. Medical Biochemistry. New York: Mosby Elsevier; 2009.)

Apart from erythrocytes, all human cells possess mitochondria. These organelles account for nearly all of total body oxygen consumption and are responsible for >90% of ATP production.[8] Although mitochondria participate in many cellular processes other than ATP production, this chapter focuses on their role as the bioenergetic powerhouse of the cell. An alternative end production of oxygen consumption is the formation of reactive oxygen species (ROS); this too will be discussed. Mitochondrial involvement in cell signaling, heat production, calcium regulation, hormone synthesis, cell death pathways, and genomic/epigenomic expression are reviewed elsewhere.[8,9]

A typical human adult male consumes approximately 380 liters of oxygen per day, with well-conditioned athletes achieving rates up to 10 times higher.[10] Oxygen serves as the final electron receptor at the terminal complex of the mitochondrial electron transport system (ETS). Through a series of oxidation-reduction (redox) reactions, electrons are transferred through the ETS to oxygen, pumping protons from the mitochondrial matrix to the intermembrane space producing a proton motive force that is coupled to ATP production by ATP synthase (ETS complex V). Mitchell first described this *chemiosmotic principle*—the coupling of biological electron transfer to ATP synthesis—in the 1960s.[11] It is now recognized that 3×10^{21} protons per second are transferred across all of the inner mitochondrial membranes in an adult male producing ATP at a rate of 9×10^{20} molecules per second. This is equivalent to a turnover rate of 65 kg of ATP per day, with even higher rates during periods of

activity.[10]

The phosphorylation of adenosine diphosphate (ADP) to form ATP through aerobic and, to a lesser extent, anaerobic processes provides the currency for cells to perform a wide range of energy-consuming activities, such as the active pumping of solutes against a concentration gradient across a membrane barrier. The first law of thermodynamics states that the total amount of energy in a system remains constant during a chemical reaction. The second law of thermodynamics states that even though total energy does not change, the net amount of usable or *free energy* (termed *Gibbs free energy* and designated by the letter G) is always decreased—that is, a negative ΔG.[5] Chemical reactions are characterized either as those that produce energy (*exergonic* or $\Delta G < 0$) or those that consume energy (*endergonic* or $\Delta G > 0$). In living organisms, the highly complex, ordered state of homeostasis would naturally degrade to a less complex disordered state (ie, toward a negative overall ΔG) without continual cellular maintenance. By coupling energy-consuming endergonic processes to the hydrolysis of ATP to yield ADP and inorganic phosphate—an energetically favorable exergonic reaction—cells are able to drive forward critical chemical reactions that would otherwise not be possible.

Complete oxidation of nutrient fuels is accompanied by a large release of free energy that is used to produce ATP. In general, cellular respiration consists of three related series of biochemical reactions (Fig. 80.3):

1. Chemical reactions resulting in the formation of two-carbon acetyl-coenzyme A (acetyl-CoA) through glycolysis of carbohydrates, β-oxidation of fatty acids, and catabolism of amino acids

2. Metabolism of acetate to carbon dioxide in the Krebs cycle with generation of the electron-rich reducing equivalents nicotinamide dinucleotide (NADH) and flavin adenine dinucleotide ($FADH_2$)

3. Shuttling of electrons from the reducing equivalents in NADH and $FADH_2$ along the mitochondrial ETS leading to ATP synthesis and ultimately reducing oxygen to water

Although the initial catabolic steps vary among the different fuels (eg, carbohydrates, fats, and amino acids), all nutrient molecules eventually converge to a common mitochondrial pathway (Fig. 80.4).

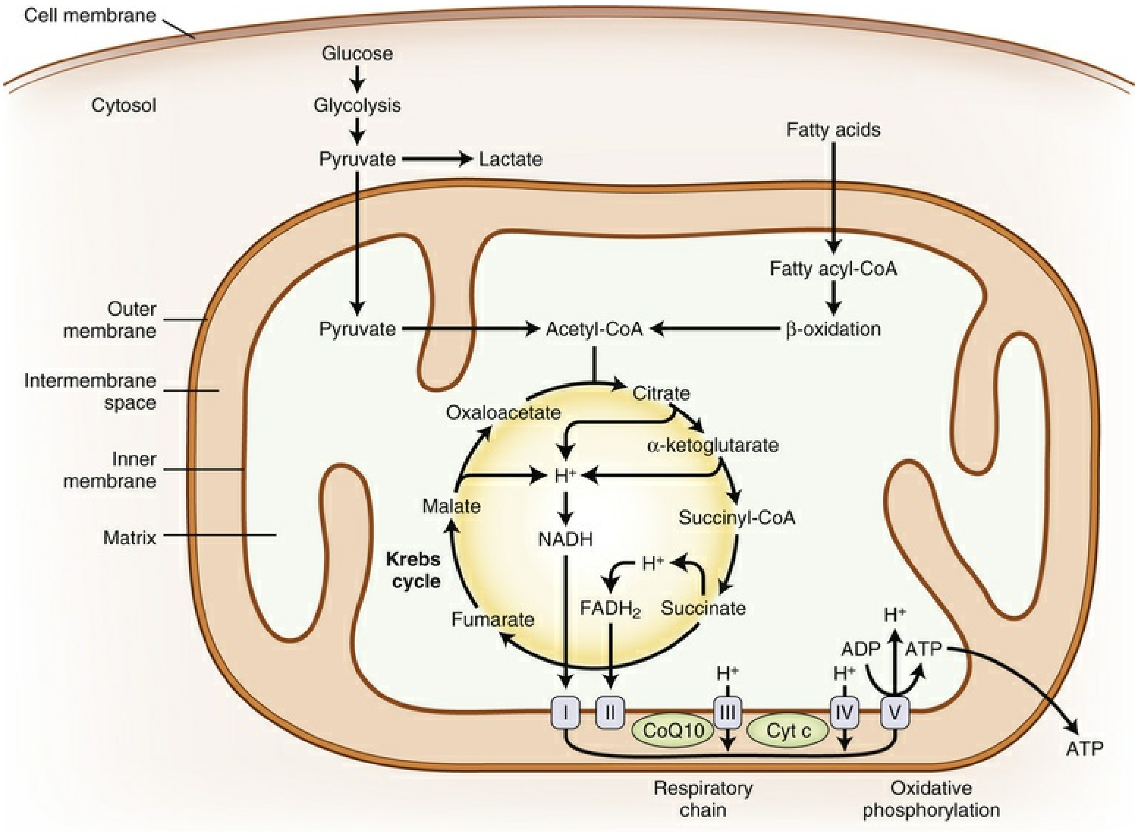

FIG. 80.3 Overview of the pathways of cellular respiration. (Modified from Genge A, Massie R. Mitochondrial structure, function, and genetics. Up-To-Date; 2013.)

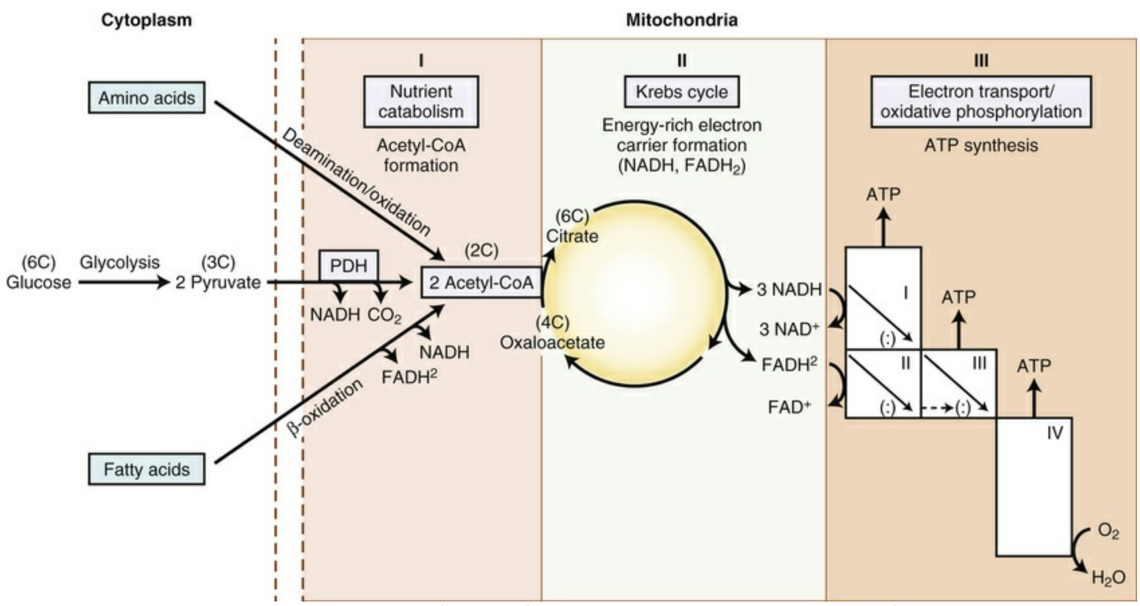

FIG. 80.4 Metabolic fates of pyruvate, the end product of glycolysis. (Modified from Baynes JW, Dominiczak MH. Medical Biochemistry. New York: Mosby Elsevier; 2009.)

Glycolysis (Anaerobic Respiration)

Glucose is the principal metabolic substrate for glycolysis and the primary fuel for many organ systems, including the central nervous system. Glucose is transported into cells via glucose transporter (GLUT) receptors and down osmotic gradients. Once in the cell, glucose enters the glycolytic pathway and is rapidly phosphorylated by the enzyme hexokinase to glucose-6-phosphate. Consequently, cellular glucose concentrations are low, allowing for a substantial favorable osmotic gradient for glucose to enter cells.[12]

Ten enzymatic reactions within the cell cytoplasm define the metabolic pathway of anaerobic respiration, termed *glycolysis*. Overall, the full sequence of glycolysis is irreversible and exergonic such that the free energy extracted from glucose is used to synthesize two net molecules of ATP, two molecules of NADH, and two molecules of pyruvate. Under aerobic conditions (ie, when oxygen is available), pyruvate is shuttled into the mitochondrial matrix through a specific low K_m transporter where it is metabolized by *pyruvate dehydrogenase (PDH)* to acetyl-CoA and carbon dioxide (CO_2) and NAD^+ is converted to NADH. PDH is thus a key enzyme that links cytoplasmic glycolysis to mitochondrial respiration, and its activity is controlled by the overall energy state of the cell through feedback regulation by both PDH kinase and PDH phosphatase. Inhibition of PDH activity occurs with elevated ratios of $NADH/NAD^+$, ATP/ADP, and acetyl-CoA/CoA ratios indicating an energy-replete state, thus helping to maintain bioenergetic homeostasis. Alternatively, under anaerobic conditions, pyruvate is reduced by NADH to lactate by *lactate dehydrogenase (LDH)* in order to regenerate the NAD^+ needed to continue glycolysis. During periods of hypoxemia, anaerobic respiration through glycolysis can be increased for a limited time to generate ATP in the absence of oxygen. However, glycolysis alone results in a net generation of only two ATP molecules compared to the much more efficient process of oxidative phosphorylation described later.[13]

Fatty Acid β-Oxidation

Fatty acids are primarily oxidized through β-oxidation in the mitochondrial matrix. Entry of long-chain free fatty acids into the mitochondria is dependent on the carnitine transport system, while medium-chain fatty acids and ketone bodies enter the mitochondria without carnitine. Catabolism of fatty acids by β-oxidation sequentially removes two-carbon units from the carboxyl terminal to generate one molecule of acetyl-CoA, one $FADH_2$, and one NADH for each two-carbon fatty acid fragment cycle. Like carbohydrate metabolism through glycolysis, lipid metabolism is a tightly regulated process. Lipid stored in adipose tissue cycles continuously between triglycerides and free fatty acids. When glucose and insulin concentrations are high (eg, after a meal), fatty acid uptake into adipocytes is increased, resulting in the synthesis and storage of triglycerides. In contrast, when glucose levels are low (eg, during starvation), up-regulation of catecholamines and glucagon stimulate lipases that release free fatty acids into the circulation to be used directly by peripheral tissues as fuel for the Krebs cycle or are transported to the liver to be converted into ketone bodies in the liver. The ketone bodies, acetoacetate and β-hydroxybutyrate, are important substrates for oxidative phosphorylation in most tissues, including the heart, brain, kidney, and skeletal muscle. Because generation of acetyl-CoA by fatty acid β-oxidation (either directly or through catabolism of ketone

bodies) occurs independent of pyruvate dehydrogenase, lipids provide an alternative fuel for oxidative phosphorylation when glucose metabolism is rate limited.[14]

Protein Catabolism

Although typically protected as a fuel source, amino acids can be mobilized for energy production in times of energy need (such as starvation or critical illness).[15] As part of the metabolic stress response mediated by a decrease in insulin and up-regulation of cortisol, catecholamines, tumor necrosis factor-α, and interleukins (IL)-1 and IL-6, protein degradation can occur with release of amino acids from skeletal muscle (see also Chapter 81). Ten of the 20 amino acids enter the Krebs cycle by way of acetyl-CoA, whereas others enter through various Krebs cycle intermediates, usually α-ketoglutarate and succinyl-CoA.[13] Alternatively, amino acids (alanine and glutamine in particular) can feed gluconeogenesis, a costly process that requires four ATP molecules plus two guanosine triphosphate (GTP) molecules and two NADH molecules to regenerate one molecule of glucose from two molecules of pyruvate. The ATP and GTP for these series of reactions are provided through β-oxidation of fatty acids.

Krebs Cycle

The Krebs cycle summarizes a circular series of nine reactions that occur in the mitochondrial matrix in which acetyl-CoA derived from glycolysis, β-oxidation, or protein catabolism is metabolized to two molecules of CO_2, one molecule of GTP, three molecules of NADH, and one molecule of $FADH_2$ (see Fig. 80.3). GTP is equivalent to ATP in terms of energy charge and is ultimately converted to ATP by the enzyme nucleoside diphosphokinase. Although oxygen itself is not part of the Krebs cycle, its presence at the end of the mitochondrial electron transport system ensures recycling of NAD^+ and FAD required in the Krebs cycle.

The first step in the Krebs cycle catalyzes the formation of the six-carbon citrate molecule (hence the alternative name of the Krebs cycle is the *citric acid cycle*) from the two-carbon acetyl-CoA and four-carbon oxaloacetate. This reaction is catalyzed by the enzyme citrate synthase and is the rate-limiting step of the Krebs cycle. With each revolution of the cycle, the fuel substrate that entered the cycle as acetyl-CoA is completely oxidized to CO_2 and water and oxaloacetate is regenerated to again react with a new acetyl-CoA molecule.

Mitochondrial Oxidative Phosphorylation

Some 2 billion to 4 billion years ago, aerobic bacteria invaded and subsequently colonized a form of primordial eukaryotic cells that lacked the ability to use oxygen. Over the ensuing millions of years, a critical symbiotic relationship developed between the cell and the aerobic bacteria that have remained steadfast through evolution.[16,17] The cell nucleus has evolved to regulate structure and overall cell function, while the oxygen-consuming bacteria formed mitochondria specialized in the energy production necessary for the development of increasingly complex species, including humans. Despite extensive intercommunication between mitochondria and its nuclear-cytosol host, mitochondria have retained many features characteristic of their bacterial origins: (1) mitochondria only arise from

other mitochondria; (2) mitochondria maintain their own genome that, in contrast to eukaryotic nuclear DNA, is circular in structure, lacking in associated histones, and is replicated up to dozens of times; (3) mitochondria synthesize their own proteins that, like bacterial proteins, exhibit *N*-formyl methionine; and (4) many antibiotics that inhibit protein synthesis in bacteria are also toxic to mitochondria.[10] The independent mitochondrial genome, located within the mitochondrial matrix, contains genes that encode 37 proteins involved in the ETS, enzymes comprising the Krebs cycle, fatty acid β-oxidation, and pyruvate oxidation and the machinery needed for mitochondrial gene translation.[17] Notably, nuclear DNA encodes approximately 1500 additional mitochondrial proteins, including 79 of the 92 subunits of the ETS complexes.[18]

Mitochondrial oxidative phosphorylation is fueled by pairs of elections originating from NADH and $FADH_2$ that are produced through the series of metabolic pathways described previously (Fig. 80.5). These electrons are shuttled along the mitochondrial ETS, ultimately reducing oxygen to water.[8] To capture as much of the energy released in a usable form when strong reducing agents such as NADH and $FADH_2$ react with a powerful oxidizing agent such as oxygen, mitochondria "step down" the reducing potential of these molecules through a controlled series of intermediate compounds in the ETS with progressively lower reducing potentials.[5] Five complexes of proteins and cytochromes embedded within the inner mitochondrial membrane comprise the ETS, including NADH dehydrogenase–ubiquinone oxidoreductase (complex I), succinate dehydrogenase–ubiquinone oxidoreductase (complex II), ubiquinone–cytochrome c oxidoreductase (complex III), cytochrome c oxidase (complex IV), and ATP synthase (complex V). The cofactors ubiquinone (coenzyme Q10) and cytochrome c facilitate the transfer of electrons from complexes I and II to complex III and from complex III to complex IV, respectively. Electrons in the form of hydride ions from NADH and $FADH_2$ cascade along these protein/cytochrome complexes toward complex IV where they are finally passed to molecular oxygen, generating water. Protons generated during these reactions are pumped across the inner mitochondrial membrane by complexes I, III, and IV, generating a proton motive force. The resulting electrochemical gradient across the inner mitochondrial membrane drives ATP synthesis by the *chemiosmotic principle*. Energy for ATP synthesis arises from an influx of these protons back into the matrix through the rotary motor of ATP synthase (complex V).[19] For each pair of electrons involved in one hydride equivalent, three molecules of ATP are produced. This process is termed *oxidative phosphorylation* because the reduction of molecular oxygen to water is linked to the addition of inorganic phosphate to ADP producing the high-energy terminal pyrophosphate in ATP. Aerobic respiration through oxidative phosphorylation is up to 15 times more efficient than anaerobic metabolism, producing 30 to 34 ATP molecules compared to only 2 ATP molecules per 1 molecule of glucose through glycolysis alone. ATP molecules are transferred out of the mitochondria through a specific adenine nucleotide translocase (ANT) antiporter on the inner mitochondrial membrane and through a voltage-dependent anion channel (VDAC) on the outer mitochondrial membrane for use as energy currency for all cellular functions. The overall metabolism of glucose through cellular respiration can be summarized as follows (the negative ΔG indicates that the overall reaction can occur spontaneously):

$$\text{Glucose} + 6\,O_2 \rightarrow 6\,CO_2 + 6\,H_2O + \text{heat}$$
$$\Delta G = -2880\ \text{kJ per molecule of glucose}$$

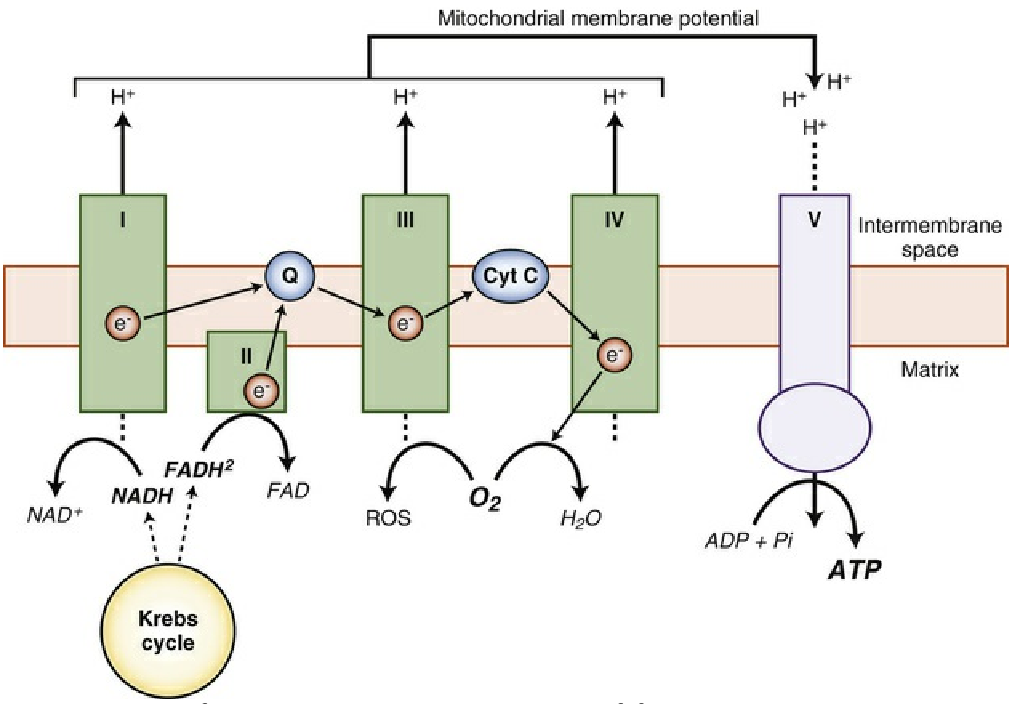

FIG. 80.5 Oxidative phosphorylation and ROS production through the mitochondrial electron transport chain. (Modified from Protti A, Singer S. Bench-to-bedside review: potential strategies to protect or reverse mitochondrial dysfunction in sepsis-induced organ failure. Crit Care. 2006;10:228.)

Although multiple regulatory steps exist along the pathways of cellular respiration, the following three are preeminent:

1. Oxygen availability to serve as the ultimate electron acceptor

2. Availability of nutrient metabolism to generate reducing equivalents in the form of NADH and $FADH_2$

3. The overall cellular energy state defined by the ratios of $NADH/NAD^+$, ATP/ADP, and acetyl-CoA/CoA

Oxygen Toxicity

In health, approximately 1% to 2% of oxygen consumption is directed toward the production of reactive oxygen species (ROS) and an even greater amount is "uncoupled" from energy production and lost as heat.[2] Heat production varies substantially from tissue to tissue, being low in the heart and much higher in skeletal muscle and brown fat.[20] Despite the terminology, uncoupling is itself a controlled process regulated by a series of uncoupling proteins (UCPs) that insert within the inner mitochondrial membrane and provide an alternative pathway for protons to move back into the matrix bypassing ATP synthase. For example, UCP-1 present in

brown fat provides a vital source of heat generation for neonates and hibernating mammals.[21]

Successive one-electron additions to molecular oxygen result in the production of superoxide anion, hydrogen peroxide (H_2O_2), hydroxyl radical, and water, respectively.[22] The partially reduced oxygen compounds are referred to as *reactive oxygen species* and are responsible for the so-called *antagonistic pleiotropy* characteristic of oxygen.[23] Under normal conditions, small amounts of constitutively produced ROS, primarily in the form of H_2O_2, are necessary for a variety of intracellular signaling pathways. Production of ROS occurs by multiple mechanisms, but the following four are prominent:

1. Mitochondrial electron transport bleed (approximately 1% to 2% of all electrons shuttled across mitochondrial complexes I, II, and III produce partially reduced oxygen species)[24]

2. Nicotinamide adenine dinucleotide phosphate (NADPH) oxidoreductases and the related cytochrome P450 oxidation reactions[25]

3. Xanthine oxidase (primarily during reperfusion following ischemic events)[26]

4. Cyclooxygenase and lipoxygenase pathways in the metabolism of arachidonic acid[27]

It has been estimated that approximately 2 billion molecules of superoxide anion and hydrogen peroxide are produced per cell per day. An antioxidant repertoire that includes superoxide dismutase, catalase, glutathione peroxidase, uric acid, vitamin C, and vitamin E counteracts this oxidant stress. Under conditions of metabolic, infectious, or inflammatory stress, ROS production can increase substantially. Although the majority of cellular ROS is sequestered within the mitochondria—thereby protecting the redox state of other intracellular molecules—such an increase can quickly outstrip availability of antioxidant defense mechanisms and cause oxidant injury to cellular proteins, lipids, and DNA.[22]

Nitrogen is also involved in the generation of another group of toxic metabolic moieties known as *reactive nitrogen species (RNS)*. Nitric oxide (NO) is known to be generated from at least four NO synthase (NOS) isoenzymes, including constitutive, inducible, neuronal, and mitochondrial forms.[28] NO is believed to play a role in mitochondrial respiration through the formation of nitrosyl complexes with various iron-sulfur center enzymes in the ETS as well as through direct competition with oxygen for binding at the heme *a,a3* active site of cytochrome oxidase. In addition to direct toxicity, NO can react with the superoxide anion to form the powerful oxidant peroxynitrite. Peroxynitrite has been demonstrated to be involved in lipid peroxidation of cell and organelle membranes, damage to various elements of the mitochondrial electron transport chain and ATP synthase, inhibition of glyceraldehyde 3-phosphate dehydrogenase, injury of the sodium-potassium ATPase pump, disruption of sodium channels, production of DNA strand breaks, and activation of the poly-adenosine ribosyl phosphate system. Peroxynitrite can also irreversibly inhibit the Krebs cycle enzyme aconitase and increase mitochondrial proton leak.[28]

Increased ROS- and RNS-mediated stress can promote the formation of the mitochondrial permeability transition pore (MPTP) leading to release of pro-apoptotic proteins, including cytochrome c, into the cytoplasm.[22,29,30] This can help to trigger activation of the apoptotic pathway orchestrating cell death. Integrity of the mitochondrial ETS complexes defines a fine line between maintaining mitochondrial homeostasis and efficient respiration versus excessive ROS/RNS production, mitochondrial dysfunction, and cell death. This balance is maintained through multiple feedback signals related to mitochondrial proton and calcium concentrations, reactive oxygen species, overall mitochondrial redox state, mitochondrial membrane potential, and mitochondrial matrix pH, all of which affect the cascade of electron transfer along the mitochondrial ETS.[10]

Impaired Cellular Respiration in Critical Illness

Mitochondrial ATP production relies on a complex series of chemical reactions that, overall, are controlled by metabolic demand. During periods of rest, metabolic needs are generally reduced and less energy is required. Conversely, during periods of activity and stress, metabolic requirements increase with a concurrent rise in cellular oxygen utilization and ATP production. An increase in ATP production ensures sufficient energy is available to respond to the activity or stress and prevents the cell from depleting ATP levels below a critical threshold that can trigger apoptotic and necrotic cell death pathways. With an acute decrease in oxygen delivery to tissues, such as with cardiac arrest, shock, or hemorrhage, mitochondrial energy output will necessarily fall. A concurrent increase in anaerobic respiration through glycolysis will attempt to partially offset the decline in ATP production through oxidative phosphorylation, but if oxygen delivery is not rapidly restored, bioenergetic homeostasis will be perturbed, leading to eventual cell injury and organ dysfunction.[2]

In critical illness, shock represents the imbalance balance between oxygen (and substrate) delivery and oxygen (and substrate) utilization such that cellular metabolic demands are not met. Early in the course of shock and other inflammatory conditions, the total body metabolic rate rises with the surge in catecholamine and catabolic hormones. In healthy volunteers, injection of endotoxin leads to a systemic inflammatory response characterized by fever and a rapid rise (within hours) in total-body oxygen consumption.[31] Over time, total body oxygen consumption and energy expenditure decrease with increasing illness severity in both animal models and critically ill patients.[32] Following trauma, failure to attain a low-normal level of oxygen consumption has been associated with increased risk of multiorgan dysfunction.[33] Survivors of critical illness subsequently demonstrate a return of oxygen consumption toward baseline levels.[32]

Changes in total body oxygen consumption and energy expenditure suggest that mitochondrial respiration is altered in critical illness. The inability of cells to effectively utilize oxygen to generate ATP is termed *cytopathic hypoxia*.[3,5] To date, most studies have focused on sepsis, though increasing evidence supports the development of cytopathic hypoxia after trauma, brain injury, and cardiac arrest. Ultrastructural mitochondrial abnormalities in a variety of organ systems have been recognized in in vivo, ex vivo, and in vitro models of sepsis for over 30 years.[34] For example, Crouser and associates demonstrated marked swelling and disruption of

mitochondrial architecture in the liver following cecal ligation and puncture (CLP) in a mouse model (Fig. 80.6).[4] Morphologic abnormalities have also been noted in mitochondria taken from heart, kidney, liver, endothelial cells, intestinal epithelial cells, and skeletal muscle in animal models of sepsis.[35] In human sepsis, heart and liver biopsies obtained immediately postmortem from adult nonsurvivors similarly show swollen and damaged mitochondria.[36]

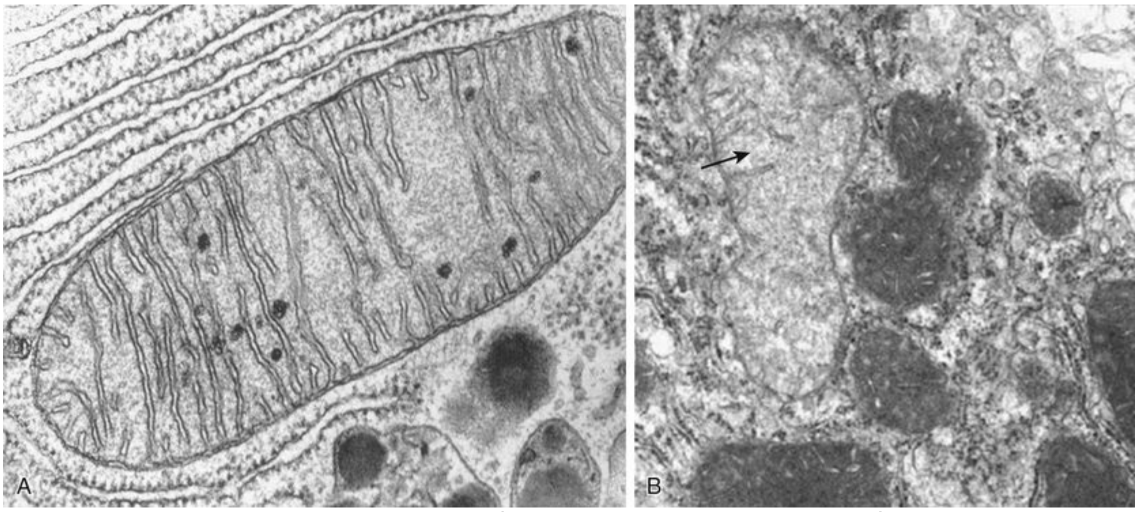

FIG. 80.6 Electron micrograph of a mitochondrion at the site of cellular respiration. (A) A normal invaginated cristae membrane provides the scaffolding for components of the electron transport chain. (B) Disrupted and edematous mitochondrial architecture observed in the liver 24 hours after cecal ligation and puncture in a mouse. (Modified from Crouser ED. Mitochondrial dysfunction in septic shock and multiple organ dysfunction syndrome. Mitochondrion. 2004;4:729-741.)

Functional alterations in mitochondrial respiration have been more variably reported as increased, decreased, or unchanged in short-term sepsis models. However, longer-term models that may better align with human critical illness more consistently demonstrate depressed mitochondrial function. In human sepsis, most —but not all—studies demonstrate decreased mitochondrial oxygen consumption in both immune and nonimmune cells.[2,37,38] For example, in a study of pediatric patients with septic shock and multiorgan dysfunction, direct measurements of mitochondrial respiration in peripheral blood mononuclear immune cells (PBMCs) showed that spare respiratory capacity—which reflects the ability of the ETS to keep pace with a rise in energy demand—was decreased and mitochondrial uncoupling was increased compared to noninfected controls.[38] Similar findings have been reported in PBMCs in adults with sepsis,[39] though one study demonstrated a progressive increase in mitochondrial respiration from day 1 to day 2 through day 6 to day 7 of sepsis compared to healthy controls.[37]

When considering bioenergetic impairment in sepsis, investigators have most commonly focused on NADH dehydrogenase–ubiquinone oxidoreductase (complex I) and cytochrome oxidase (complex IV). As the largest complex of the ETS, complex I is subject to impairment from changes in a variety of protein subunits. Multiple studies have demonstrated decreased activity of ETS complex I in sepsis models and in humans.[40,41] Complex IV contains two heme subgroups (cytochrome *a* and *a3*) that

assist in the final transfer of electrons to reduce oxygen to water. A reduced cytochrome *a,a*3 redox state in the absence of tissue hypoxia indicates a defect in mitochondrial oxygen use and suggests impaired oxidative phosphorylation. A number of investigators have demonstrated reduced cytochrome *a,a3* redox status during endotoxemia and gram-negative bacteremia in the heart, brain, skeletal muscle, and intestine in a variety of animals.[42,43] In addition, decoupled cytochrome *a,a3* was more likely in adults who did versus did not develop multiorgan system dysfunction following trauma, despite normalization of oxygen delivery.[44] In baboons following *Escherichia coli* infusion, myocardial cytochrome oxidase activity decreased to 51% of baseline.[45] Steady-state levels of cytochrome oxidase subunit I messenger RNA (mRNA) and protein are also decreased in the murine heart following CLP.[43] Interestingly, Verma and colleagues demonstrated that when complex IV activity is stimulated by administration of caffeine, myocardial function and survival improved after cecal ligation and puncture in a rodent model.[46]

Despite structural, biochemical, and functional evidence for mitochondrial dysfunction in sepsis, trauma, and other critical illness, the literature is less clear regarding these effects on tissue ATP availability. Several studies have reported preservation of ATP levels in septic myocardium, but others have shown decreased high-energy phosphates with endotoxemia.[2,5] In a study of 28 human adults with severe sepsis, 12 (43%) of whom died of sepsis-related MODS, nonsurvivors had lower levels of ATP in skeletal muscle compared to survivors.[40] However, even preservation of ATP does not imply an absence of mitochondrial dysfunction in sepsis.[47] When oxygen delivery and cellular hypoxia are limited (as in shock), cells may adapt to maintain viability by down-regulating oxygen consumption, energy requirements, and ATP demand.[2,5,9] Thus, a fall in ATP utilization may help to preserve ATP even if energy production is diminished. In the heart, this response is referred to as *myocardial hibernation* and classically occurs following an acute coronary syndrome. If cellular metabolic activity continued unchanged despite mitochondrial dysfunction, then ATP levels would inevitably diminish and cell death pathways would be activated. Because cell death does not appear to be a primary feature of sepsis-induced organ dysfunction, it follows that cells may instead adapt to cope with the falling energy supply.[34,48] Thus, finding preserved ATP during sepsis reveals little about the integrity of oxidative phosphorylation.

Though experimental data demonstrate an association of pro-inflammatory cytokines and ROS/RNS production with mitochondrial dysfunction, the precise etiology by which mitochondrial function is altered in critical illness remains unclear. A number of mutually compatible mechanisms may contribute to a clinical state of cytopathic hypoxia under pathologic conditions, including the following:

1. Decreased tissue oxygen (and substrate) delivery impairing oxidative phosphorylation

2. Inhibition of PDH with decreased flux of acetyl-CoA through the Krebs cycle

3. NO-mediated inhibition of ETS complexes

4. Peroxynitrite-mediated inhibition of the Krebs cycle and ETS complexes I, II, and V

5. Depletion of cellular NADH due to activation of the enzyme poly(ADP-ribose) polymerase (PARP)-1 in response to ROS-mediated nuclear DNA damage

6. Insufficient mitochondrial turnover due to impaired mitochondrial biogenesis, fission/fusion, or mitophagy

7. Hormonal alterations, including relative hypothyroidism

8. Pharmacologic inhibition of mitochondrial function as a side effect of many drugs commonly used in the intensive care unit setting, including some antibiotics, catecholamines, and sedatives (propofol in particular)

Injection of lipopolysaccharide (LPS) endotoxin into healthy human volunteers also results in widespread suppression of genes regulating mitochondrial energy production and protein synthesis.[49] Differential expression of mitochondrial genes in blood cells has been reported for several diseases in which bioenergetic failure is a postulated mechanism.[50,51] In a study of adult sepsis, decreased ETS gene expression correlated with impaired activity of ETS complexes I and IV in skeletal muscle.[52] In pediatric sepsis, suppression of nuclear-encoded mitochondrial genes was greatest in the subgroup of patients with the highest rates of MODS and death.[53]

Accumulating evidence also supports a propagative role for mitochondrial damage to feed-forward the systemic inflammatory response and contribute to distant organ injury in trauma and sepsis.[9] Oxidative injury due to an increase in mitochondrial ROS and RNS can fragment mitochondrial DNA (mtDNA). Oxidatively damaged mtDNA fragments can be exported from the mitochondrial through the MPTP to the cytosol or the extracellular space. In the cytosol, mtDNA promotes the formation of the Nod-like receptor-P3 (NLRP3) inflammasome, a supramolecular platform that activates caspase-1 and increases the release of the proinflammatory cytokines IL-1β and IL-18.[54] In the circulation, mitochondria are recognized by the innate immune systems as a danger-associated molecular pattern (DAMP) via the pattern recognition receptor, TLR [toll like receptor]-9, due to their evolutionary similarities with bacterial pathogens.[55] Several studies in human sepsis and trauma have demonstrated that an increase in circulating levels of mtDNA is associated with adverse outcomes.[55,56] Consequently, mtDNA has been proposed as a potential novel biomarker linked to mitochondrial dysfunction in critical illness.

Despite demonstration of altered mitochondrial structure and function, there is actually little evidence that impaired mitochondrial respiration *causes* organ dysfunction in critical illness. In fact, the decrease in oxygen utilization and overall metabolic rate seen in sepsis parallels similar physiologic changes observed in hibernating mammals that reduce their metabolism to promote survival amid decreased substrate availability.[48] Indeed despite physiologic and biochemical mitochondrial dysfunction in many tissues recovered from animal models and human patients with sepsis, there tends to be minimal evidence of cell death in dysfunctional organ systems. Moreover, survivors of critical illness rapidly recover organ function. Therefore, although a profound and prolonged metabolic down-regulation can trigger cell death, the observation that mitochondrial hibernation is a conserved physiologic response across models and species suggests that some degree of transient energetic swoon early in sepsis (and other critical illnesses) could be an adaptive response to ischemia, hypoxemia, and shock.[2,48,57] The use of induced

hypothermia to decrease metabolic demand and protect vital organs during cardiopulmonary bypass and following cardiac arrest supports the notion that a decrease in metabolic demand may help to restore bioenergetic homeostasis when oxygen (and substrate) delivery—and thus ATP production—is limited. Although this may manifest clinically as organ dysfunction, protected bioenergetic homeostasis may help to prevent cell death and offer the prospect of organ recovery once oxygen (and substrate) supply is restored.[2]

Clinical Assessment of Oxygen Utilization

Biochemical pathways and cellular energetics may seem far removed from the daily care of patients in the pediatric intensive care unit, where discussions about the respiratory and circulatory systems seem to dominate. However, at its core, the goal of critical care medicine is to maintain and support the basic physiologic functions of the patient until his or her own homeostasis returns. This means that the underlying goal of cardiopulmonary and other organ support is to optimize cellular function, and that function requires energy derived from the metabolism of oxygen.

Inherent in this goal is the need to assess the adequacy of oxygen delivery and utilization at the bedside. Traditional markers, such as blood pressure, capillary refill, and urine output, are used to evaluate hypoperfusion but are not sensitive or specific indicators of tissue metabolic stress or impaired oxygen utilization. Several monitoring techniques are available, but all have important physiologic or practice limitations.

Lactate

Lactate is a commonly used surrogate for tissue hypoxia, as it is produced as a byproduct of anaerobic metabolism. In general, lactic acidosis occurs when there is an imbalance between production and clearance of lactate. Measurement of lactate in human blood was first described in 1843 in a lethal case of fulminant septic shock due to puerperal fever in a young woman.[58] Blood lactate monitoring is frequently performed in critically ill patients, usually with the aim of detecting tissue hypoxia leading to anaerobic respiration, traditionally termed *type A lactic acidosis*. In this case, increased lactate production is presumed to reflect impaired oxidative phosphorylation in the absence of sufficient oxygen available to the mitochondria such that glycolysis-derived pyruvate is shuttled through LDH to lactate to regenerate the NAD^+ needed to continue anaerobic ATP production.[59] However, other processes not related to tissue hypoxia can also result in increased blood lactate levels, such as with excess adrenergic stimulation that increases aerobic glycolysis and pyruvate production beyond the rate of mitochondrial metabolism (termed *type B lactic acidosis* and common in severe asthma or therapy with epinephrine), impaired PDH activity, or delayed lactate clearance seen in patients with hepatic dysfunction.[60-62] Although lactic acidosis is often associated with a high anion gap and is generally defined as a lactate level greater than 5 mmol/L and a serum pH less than 7.35, the presence of hypoalbuminemia may mask the anion gap and concomitant alkalosis may raise the pH. As originally reported by Huckabee, normal arterial blood lactate is approximately 0.620 mmol/L and venous lactate is

slightly higher at 0.997 mmol/L.[63]

During anaerobic conditions, pyruvate derived from the conversion of glucose cannot enter the Krebs cycle via acetyl-CoA to produce energy. Instead, pyruvate is converted into lactate, known as the *Pasteur effect*. The normal lactate/pyruvate ratio is approximately 20 : 1, and it rises under hypoxic conditions as lactate production increases. The causal relationship between anaerobic hyperlactatemia and tissue hypoxemia has been confirmed by experimental and clinical studies demonstrating that limiting oxygen consumption (VO_2) by decreasing oxygen delivery (DO_2) below a threshold coincides with a sharp increase in lactate levels.[59,64] Accordingly, in the early phase of septic shock, hyperlactatemia is accompanied by oxygen supply dependency,[65] and several studies have found that initial lactate correlates with increased mortality.[66,67] Moreover, lactate clearance of 10% or more during the early hours of sepsis resuscitation predicts survival,[67,68] and an elevated blood lactate concentration may be sufficient evidence that tissue perfusion is inadequate, even if hypotension is not present (so called *cryptic shock*).[69] On the other hand, in a study of 123 adult patients with vasopressor-dependent septic shock, 45% were found to be "nonlactate expressers" (defined as a lactate <2.4 mmol/L), but mortality remained high at 20% in these patients.[70] In pediatrics, hyperlactatemia appears to be less common overall than in adults with septic shock.[71] Thus, though hyperlactatemia has been associated with increased risk of organ dysfunction, need for resuscitative therapies, and has been independently associated with in-hospital mortality,[72,73] the absence of an elevated lactate should not slow ongoing aggressive resuscitative efforts in children with other indices of altered perfusion.

Despite wide availability and an association with both global tissue hypoxia and poor outcome, no data are currently available to support monitoring lactate levels beyond the immediate resuscitative period, especially once DO_2 has been restored. The numerous etiologies of increased lactate and the lack of sensitivity and specificity for regional tissue perfusion and respiration remain important limitations in using lactate to monitor cellular bioenergetics. A common clinical scenario occurs during volume resuscitation of patients (iatrogenic hyperchloremia) or epinephrine infusions, in which a chloride load and type B lactic acidosis are interpreted as ongoing shock, thus prompting additional fluid and more vasoactive-inotropic support. This scenario may initiate a vicious cycle with the potential for overresuscitation.[74] The treatment of the patient with lactic acidosis should therefore be aimed at the underlying disease, with resuscitation guided by the overall clinical improvement of the patient and not just the lactate concentration itself. Accordingly, the routine daily measurement of serum lactate levels in critically ill patients remains controversial.

Venous Oxygen Saturation

DO_2 is defined as the product of the arterial oxygen content of the blood and the cardiac output (1):

$$DO_2 = CO \times CaO_2$$
$$\text{where } CaO_2 = (1.34 \times Hb \times SaO_2) + (0.003 \times PaO_2)$$

and CO is cardiac output, CaO_2 is arterial oxygen content, Hb is the hemoglobin concentration, SaO_2 is the arterial oxyhemoglobin saturation, and PaO_2 is the arterial oxygen tension. Given that the amount of dissolved O_2 is so small, it is often dropped from the calculation for simplicity. Derivation of cardiac output is described elsewhere in this text (see Chapter 85). VO_2 is defined as the amount of oxygen extracted by the body from the blood and, according to the Fick principle, is calculated by the difference between the CaO_2 and the CvO_2 (the oxygen contents of arterial and mixed venous blood) multiplied by the cardiac output (2):

$$VO_2 = CO \times (CaO_2 - CvO_2)$$
$$\text{where } CvO_2 = (1.34 \times Hb \times SvO_2) + (0.003 \times PvO_2)$$

In the normal, healthy state DO_2 is in significant excess of VO_2. That is, the blood is carrying an excess of oxygen compared with the amount of oxygen the body needs. The ratio of consumption to delivery is called the oxygen extraction ratio (ERO_2) and is calculated as follows (3):

$$ERO_2 = (CaO_2 - CvO_2)/CaO_2$$

Given that typical SvO_2 is approximately 65% to 75%, the ERO_2 is typically 0.25 to 0.35. This means that delivery normally exceeds consumption by a factor of 2 to 3. Thus, a buffer exists where decreases in cardiac output are well tolerated across a certain range such that an increase in ERO_2 ensures that VO_2 remains unaffected by changes in DO_2. There is a point, however, at which the oxygen extraction capabilities of the tissues are exceeded. At that point, VO_2 becomes dependent on DO_2. This biphasic relationship of DO_2 and VO_2 is shown in Fig. 80.7.

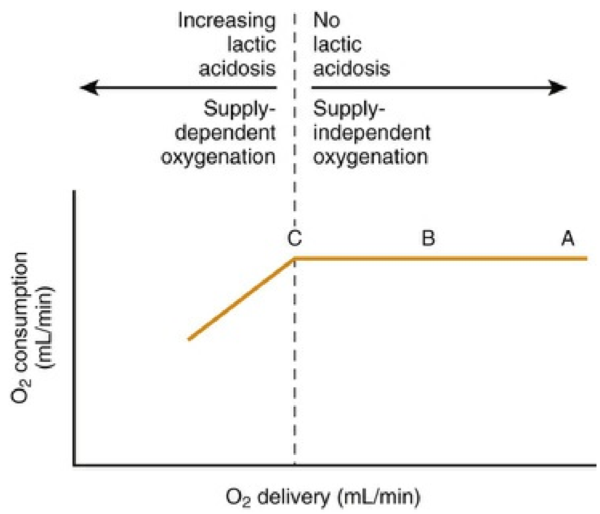

FIG. 80.7 Biphasic relationship between oxygen delivery and oxygen consumption.

Bedside evaluation of DO_2 and VO_2 would be of great value to the clinician. Unfortunately, most of the methods of calculating VO_2 rely on cardiac output (via the Fick principle), which results in a situation where a single measured variable is included in two parts of a regression analysis, so-called mathematical coupling. This dependency leads to amplification of any error in that measurement and may result in an apparent relationship between variables that does not truly exist. Other methods to measure VO_2 in intubated critically ill patients require use of a metabolic cart,[75] but routine use is currently lacking. As in many areas of critical care medicine, when something cannot be measured directly, a surrogate measure must be used.

In practice, the central venous or mixed venous oxygen saturation ($ScvO_2$ or $SmvO_2$) can be used as a continuous or intermittent measure to assess the global balance of oxygen delivery and consumption in a patient with septic shock.[76] As central venous catheters have largely replaced the use of pulmonary arterial catheters, particularly in pediatrics, $ScvO_2$ is now more commonly measured than $SmvO_2$.[77] $ScvO_2$ is ideally measured from a catheter with its tip at the superior vena cava–right atrial junction. Measurements taken from a femoral catheter with its tip in the inferior vena cava are thought to be less reliable due to greater variability in splanchnic oxygen utilization.[78] An $ScvO_2$ <70% indicates that tissue oxygen extraction is increased from normal, suggesting inadequate oxygen delivery due to either low cardiac output, decreased arterial oxygen content, or both.[76] Such a finding should prompt one to consider therapies to improve oxygen delivery either through additional fluid administration, vasoactive therapy, or an increase in arterial blood oxygen content.[79] However, $ScvO_2$ may also be low if oxygen utilization is increased, as in states of high metabolic demand (eg, fever in sepsis, seizure, or hyperthyroidism). Alternatively, elevated $ScvO_2$ >80% suggests that oxygen utilization may be impaired due to mitochondrial dysfunction, reflecting a global state of cytopathic hypoxia.[5]

In a trial of early goal-directed therapy in adult septic shock by Rivers and colleagues,[79] an $ScvO_2$ >70% was targeted as a primary hemodynamic end point. Although three more recent trials failed to demonstrate benefit from routine $ScvO_2$ monitoring,[80-82] an $ScvO_2$ >70% remains the recommended target in current pediatric shock guidelines.[41] A pediatric trial in children with fluid refractory shock found that targeting an $ScvO_2$ >70% for 72 hours compared to standard therapy reduced mortality from 39.2% to 11.8% ($p = 0.002$).[71] Furthermore, in a pediatric prospective cohort trial evaluating the effect of intermittent $ScvO_2$ monitoring on 120 children with fluid refractory septic shock, children who had intermittent $ScvO_2$ monitoring performed at 1, 3, and 6 hours had significantly lower in-hospital mortality (33% versus 55%, $p = 0.02$) and a reduction in the number dysfunctional organs (two versus three, $p < 0.001$).[83]

An important limitation of $ScvO_2$ is the need for central venous access, making this laboratory value difficult to obtain in many children who may not otherwise require such an invasive procedure. In addition, continuous $ScvO_2$ measurements require a specialized catheter that may not be available in all centers. A prospective cohort study of adult patients diagnosed with severe sepsis at three different hospitals found that mean arterial pressure and central venous pressure were still the most

important hemodynamic variables in initial hemodynamic resuscitation and that low postresuscitation SvO_2 was not associated with a worse outcome.[84] Other studies have failed to show an advantage of using $ScvO_2$ over other markers, including lactate, in predicting in-hospital mortality.[67,85] Three large randomized trials also recently failed to show that routine $ScvO_2$ monitoring improved outcomes during resuscitation of adults with septic shock.[80-82] Consequently, although both low (<70%) and high (>80%) $ScvO_2$ may provide general insight into the global state of DO_2-VO_2 mismatch, this measure, much like lactate, cannot detect tissue-specific changes in bioenergetic homeostasis.

Microdialysis

Microdialysis allows for the measurement of energy-related metabolites within the interstitial space of a regional tissue bed. This is most commonly performed using a thin, flexible catheter with a semipermeable membrane inserted into skeletal muscle. A solution of a known solute concentration is slowly pumped into the catheter, and soluble small molecules, such as glucose, lactate, pyruvate, and glycerol, equilibrate across the membrane. The fluid is then collected and analyzed as a regional measurement of cellular metabolic activity. Although it provides a more tissue-specific measure, the degree to which respiration in skeletal muscle reflects other vital organs is not clear.[86] Because blood and oxygen delivery are diverted away from skeletal muscle to critical organs (brain, heart, and kidneys) in shock, changes in muscle cellular respiration have be a sensitive indicator of inadequate systemic perfusion. Indeed, animal and human studies in sepsis and hemorrhage have demonstrated an association between microdialysis lactate/pyruvate ratios and outcome.[87,88] Further studies are needed to validate the utility of microdialysis as a clinically useful measure of cellular respiration.

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) enables continuous, noninvasive bedside monitoring of regional tissue oxygenation and mitochondrial complex IV redox state. As with pulse oximetry, NIRS is based on the principle that the oxygen-carrying pigments hemoglobin and myoglobin and cytochrome *a,a3* have well-defined absorption spectra that are influenced by oxygen binding. NIRS technology thus uses a modification of the Beer-Lambert law, which describes the relationship between absorption of light and the concentration of deoxygenated hemoglobin [Hb], oxygenated hemoglobin [HbO_2], and intracellular chromophores (cytochrome a,a_3).

Clinical utilization of NIRS to date has generally focused on monitoring tissue-specific oxy- and deoxyhemoglobin concentrations, most commonly in brain, kidney, and skeletal muscle.[89-91] Available NIRS monitors are mathematically weighted toward venous blood, thus largely reflecting deoxygenated Hb levels, and display a number (referred to as *regional* SO_2 or rSO_2) that varies with local oxygen delivery and extraction. A decrease in NIRS rSO_2 has been correlated with a fall in local tissue perfusion in animal models of shock, decreased cardiac output in infants following

cardiac surgery, and predicted fluid responsiveness in dehydrated children.[89-91] However, large variations in "normal" rSO_2 levels, the lack of defined "critical threshold" for rSO_2, and the inability of rSO_2 to differentiate between changes in DO_2 or VO_2 have limited the universal acceptance of NIRS monitoring.

In addition to hemoglobin, NIRS can assess the cytochrome a,a_3 redox state of complex IV in the mitochondrial ETS.[92] Cytochrome a,a_3 is the terminal component along the ETS that reduces oxygen to water, and it remains in a reduced state during hypoxemia. The absorption spectrum of cytochrome a,a_3 in its reduced state shows a weak peak at 700 nm, whereas the oxygenated form does not. Therefore monitoring changes in the cytochrome a,a_3 redox state can provide a measure of the adequacy of oxidative metabolism.[93] To date, however, NIRS assessment of mitochondrial redox state, while promising, remains technologically challenging and has therefore been limited to research settings.

Optical Spectroscopy

Similar to NIRS, optical spectroscopy uses absorption of light by tissues to assess concentration of various analytes of interest. By using an entire spectral region in the visible or near-infrared spectral region that includes many (up to hundreds) of wavelengths of light, it is possible to improve distinction between similar molecules. In particular, advances in optical spectroscopy have made it possible to measure the oxygenation state of myoglobin independently from that of hemoglobin despite similar absorbance spectra.[94] Myoglobin is an intracellular protein found in skeletal and cardiac muscle cells and is involved in the transport of oxygen from the cytoplasm to the mitochondria. Quantification of myoglobin saturation (percentage of total myoglobin bound with oxygen) provides a direct measure of *intracellular* oxygen availability.

Measurements of myoglobin saturation in the presence of hemoglobin, hemoglobin saturation in the presence of myoglobin, and cytochrome oxidation states have been recorded from optical reflectance spectra acquired from muscle.[95] These measurements remove the ambiguity present in conventional near-infrared spectroscopic methods in which hemoglobin and myoglobin absorbances are combined. In a guinea pig endotoxin model, ex vivo perfused hearts were noted to have higher levels of intracellular oxygenation and lower rates of oxygen consumption compared to controls supporting the concept of impaired oxygen utilization.[96] Optical spectroscopy thus has the potential to separately identify the oxygenation state in anatomically and physiologically distinct tissue regions, including the vascular (hemoglobin), cellular (myoglobin), and mitochondrial (cytochromes) levels.

Tissue Oxygen Tension

Tissue oxygen tension (tPO_2) measures the partial pressure of oxygen within the interstitial space. Traditional probes use Clark electrodes, but newer techniques are now available that can more accurately measure tPO_2 without themselves consuming oxygen. A decrease in DO_2 would be expected to lower tPO_2 whereas a

decrease in VO_2 would raise tPO_2 (so long as DO_2 levels were not concurrently diminished).[86] In sepsis models, several studies have demonstrated that skeletal muscle and mucosal tPO_2 are unchanged or increased, suggesting a fall in VO_2 either concurrent with or greater than the decrease in DO_2.[97,98] In human studies, brain tPO_2 monitoring has been demonstrated to improve outcomes following traumatic brain injury.[99] More studies are needed to determine the benefits of tPO_2 monitoring in pediatric critical illness.

NADH Fluorometry

Reduced NADH has the useful property of fluorescing in response to 340-nm excitation light, whereas the oxidized form, NAD+, does not. Changes in the emitted light are therefore proportional to the turnover NADH, which is predominately related to mitochondrial function. When oxygen utilization slows, NADH will accumulate and fluorescence will rise, though this may also occur under hypoxemic conditions. As with NIRS, however, only changes relative to an arbitrary baseline measurement can be obtained, as absolute values are not possible.[86]

Magnetic Resonance Spectroscopy

Magnetic resonance spectroscopy (MRS) uses radiolabeled molecules to noninvasively measure in vivo tissue metabolite concentrations. MRS has been used clinically for more than two decades in neurologic disorders to measure blood vessel distribution and architecture, blood flow velocity, regional perfusion and blood volume, blood and tissue oxygenation, lactate production and intracellular pH, Krebs cycle activity, and mitochondrial oxidative phosphorylation in the brain. For bioenergetic studies, phosphorus-31 MRS is primarily used to detect changes in phosphocreatine, ATP and inorganic phosphate, and certain compounds related to membrane synthesis and degradation.[100] Because phosphocreatine is the primary ATP buffer in muscle, depletion in this molecule leads to a drop in ATP levels.[100] Proton MRS can also be used to measure four markers related to oxygen metabolism: the peak of *N*-acetyl-aspartate (NAA), an amino acid present in neurons that reflects the status of neuronal tissue; creatine, found in glia and neurons, which serves as a point of reference because its level is believed to be stable; choline, a constitutive component of cell membranes that reflects glial proliferation or membrane breakdown; and lactate, a marker of anaerobic metabolism and therefore of ischemia. Elevated lactate and decreased NAA are associated with worse neurologic outcome in neonates with asphyxial injury.[101,102] Although MRS is useful for diagnosis and prognosis, it is not currently practical as a method to guide minute-to-minute patient management.

Blood Mitochondrial DNA

Under conditions of hypoxemia, ischemia, inflammation, and oxidative stress, mitochondrial damage can lead to fragmentation of mtDNA and release into the circulation. It has therefore been proposed that blood levels (both cellular and free

plasma concentrations) of mtDNA may be a biomarker of mitochondrial dysfunction and overall severity of illness.[55,103] Increased levels of blood mtDNA have been reported in adult patients with sepsis and trauma,[56,104] though methodological variability may underlie important differences between studies.[103] Circulating mtDNA may also serve as DAMP, propagating inflammation and contributing to distant organ injury as noted previously.[57]

Mitochondrial- and Bioenergetic-Targeted Therapy in Critical Illness

With increasing recognition of the central role of altered cellular respiration—and mitochondrial dysfunction in particular—in the pathogenesis of organ failure in critical illness, there has been concurrent emerging interest in the potential for metabolic- and mitochondrial-targeted therapeutic strategies to improve patient outcomes. A therapeutic strategy that partners an up-regulation or down-regulation of oxygen utilization to better match oxygen delivery may restore bioenergetic homeostasis and improve cellular—and thus organ—function. Several existing and novel agents have demonstrated potential to optimize cellular respiration and improve mitochondrial function, though questions of clinical utility remain largely unanswered at this time.

Antioxidants

As discussed earlier, ROS and RNS play essential roles in cell signaling and, as such, their activity is normally tightly regulated by a network of intracellular antioxidants. In sepsis, cardiac arrest, and other severe illnesses, the production of ROS and RNS increases sharply (largely due to alterations of the mitochondrial ETS), leading to a wide array of local cellular damage and systemic inflammation. The natural cellular antioxidant defense system includes manganese dismutase (MnSOD), glutathione (GSH), thioredoxin (TSH), catalase, peroxidase, peroxiredoxins, sulfiredoxins, cytochrome c, and peroxidase. With a large increase in ROS and RNS, these molecules may be rapidly depleted, leading to an overall imbalance of oxidative and nitrosative stress.

A wide variety of exogenous antioxidant supplements have been studied in animal models and humans with critical illness, including vitamin A, vitamin E, vitamin C, coenzyme A, selenium, melatonin, and *N*-acetylcysteine, among others. Although antioxidant supplementation can successfully reduce oxidative stress, thus far clinical trials have failed to convincingly demonstrate an outcome benefit.[105] A strategy that better targets antioxidants to the mitochondria, however, has shown some promise in preclinical studies and may be better suited for use in critically ill patients.[106,107] One example involves antioxidant molecules that are covalently joined with a lipophilic cation concentrate within the mitochondria. Such molecules, including MitoQ and MitoVitE, have been shown in vitro to protect mitochondria and whole cells from oxidative stress and have demonstrated utility to reduce organ dysfunction in animal models.[106] Similarly, a series of small synthetic positively charged peptides less than 10 amino acids in length, termed *Szeto-Schiller (SS) peptides,* can freely penetrate cell and mitochondrial membranes and have been

shown to be effective in some ischemia-reperfusion oxidative stress models.[108] Several early-phase human trials of mitochondrial-targeted antioxidants and SS peptides are ongoing.

Nitric Oxide Synthase Inhibitors

Sepsis and other inflammatory illnesses have long been associated with a marked increase in inducible NOS-production (iNOS) of nitric oxide. In addition to its role in decreasing vascular resistance in distributive shock, NO directly inhibits ETS complex IV activity and indirectly disrupts several cellular respiration pathways through up-regulation of ROS/RNS, chiefly peroxynitrite. Despite the failure of a nonselective NOS inhibitor to improve outcomes in a randomized trial in adult sepsis,[109] selective iNOS inhibitors such as NG-nitro-L-arginine methyl ester (L-NAME), have demonstrated beneficial effects on mitochondrial respiration, hemodynamic function, and organ function in animal models.[110,111]

Glycemic Control

Hyperglycemia and insulin resistance are common findings in critically ill patients. The inability of cells to utilize glucose to generate pyruvate can lead to downstream limitations of oxidative phosphorylation and results in mobilization of fat and protein stores. Since the 1990s, there has been substantial interest in the use of exogenous insulin to restore normoglycemia in adult and pediatric critical illness. Despite widespread enthusiasm following an adult trial of insulin to achieve tight glycemic control (80–110 mg/dL) that reduced ICU mortality from 8% to 4.6%,[112] subsequent studies have failed to replicate the overall benefit, including two randomized pediatric trials.[113,114] Interestingly, insulin has been shown to stimulate mitochondrial ATP production in human skeletal muscle ex vivo,[115] and maintenance of normoglycemia with insulin preserves hepatic mitochondrial structure and function in adult critical illness.[116] Thus the potential for targeted insulin therapy and glycemic control to improve cellular bioenergetic homeostasis remains unclear.

Substrate Provision

Several studies suggest that despite decreased activity complex I of the mitochondrial ETS, complex II is relatively preserved in sepsis. Complex II transfers electrons from $FADH_2$ produced from the oxidation of succinate to coenzyme Q. Consequently, supplementation of succinate may help to restore overall ETS activity and ATP production, as has been suggested in animal models of sepsis.[117] However, different insults may be prone to distinct pathophysiology and thus variable therapies. For example, in a porcine model of pediatric traumatic brain injury, mitochondrial ETS complex II exhibited the most profound decrease in activity.[118] Alternative fuels for cellular respiration, including carnitine supplementation, have shown promising results in animal models,[119] but direct evidence for benefit in humans has not yet been demonstrated. Similarly, supplementation with coenzyme Q, cytochrome c, and caffeine improves mitochondrial function in vitro and in

animal models.[43,46,120,121]

Mitochondrial Biogenesis and Mitophagy

All cells that undergo oxidative phosphorylation have robust quality control mechanisms to ensure a full complement of healthy mitochondria. Cells optimize the overall mitochondrial number, distribution, and function through a network of interrelated processes of biogenesis, fission, fusion, and mitophagy.[57] Mitochondrial biogenesis is the process of synthesizing new functional mitochondria and can be induced by oxidative stress and inflammation.[9] Depending on the stimulus, mitochondrial biogenesis is executed through several signaling pathways that converge on a common set of coactivators and transcription factors, including peroxisome proliferator-activated receptor gamma-1 coactivator alpha (PGC-1α), nuclear respiratory factors (NRF-1 and NRF-2), nuclear factor erythroid 2-related factor 2 (Nrf2), and mitochondrial transcription factor A (TFAM).[9] These proteins either increase transcription of nuclear-encoded mitochondrial proteins or are imported into the mitochondria to directly up-regulate expression of mtDNA to promote ETS complex assembly.

Data from both animal studies and septic patients have shown that mitochondrial biogenesis is associated with recovery of organ function and survival. Haden and colleagues showed that mitochondrial biogenesis is evident over 1 to 3 days following a nonlethal exposure to *Staphylococcus aureus* in a rodent model, with a subsequent recovery of oxidative phosphorylation.[122] The same group further showed that sepsis survival could be improved in rodents treated with daily exposure to a low dose of carbon monoxide.[123] Similarly, removal of dysfunctional mitochondria—termed *mitophagy*—has also been shown to be protective in sepsis. For example, in both liver and kidney of hyperglycemic critically ill rabbits, biochemical markers indicating insufficient mitophagy were more pronounced in nonsurviving animals.[124] Interestingly, after 3 and 7 days of illness, mitophagy was better preserved in animals treated with insulin to preserve normoglycemia, which correlated with improved mitochondrial function and less organ damage.[124] Pharmacologic agents that induce mitochondrial biogenesis, such as pioglitazone,[125] resveratrol,[126] and recombinant human TFAM (rhTFAM),[127] and that simulate mitophagy, such as rapamycin,[124] are currently being explored as potential therapeutic strategies to recover mitochondrial function and restore bioenergetic homeostasis in critical illness.

Membrane Stabilizers

Ultrastructural evidence of mitochondrial injury in critical illness includes damage to the inner mitochondrial membrane and organelle swelling. These features are associated with loss of the electrochemical gradient that drives ATP production through oxidative phosphorylation. Although the mechanisms underlying these physiologic changes remain incompletely understood, opening of the MPTP is believed to be involved. A number of compounds that inhibit pore opening, including cyclosporine A and melatonin, are being investigated as another approach to restore mitochondrial function through membrane stabilization.[120] For example, in

a piglet model of nonimpact rotational brain injury, administration of cyclosporine A at a clinically relevant time point ameliorated mitochondrial dysfunction and promoted a 42% decrease in injured brain volume.[118]

Hibernation

Another potential strategy to restore bioenergetic homeostasis that could be pursued in the presence of impaired cellular respiration is to suppress metabolic energy expenditure. In many hibernating mammals, a purposive metabolic down-regulation is a crucial response that facilitates tolerance to a lack of energetic substrates during harsh environmental conditions and promotes survival.[128,129] The hibernating state prevents a cellular bioenergetic crisis by reducing demand for ATP when substrate or oxygen supply is low and decreases mitochondrial oxidative stress. Although humans do not hibernate and have only a limited tolerance to diminished oxygen or substrate delivery to vital organs, the impairment in cytochrome oxidase activity observed during sepsis mimics that of true hibernation, suggesting that, at least early on, such impairment may be an adaptive response to an inflammatory insult.[48] Following myocardial ischemia, as in adult coronary artery disease, a transient decrease in myocardial contractility—termed *myocardial hibernation*—has been well described, with subsequent functional recovery if adequate perfusion is promptly restored.

Attempts to reduce metabolic demand through induced moderate hypothermia after neonatal hypoxic-ischemic injury, cardiac arrest, traumatic brain injury, and hyperammonemic metabolic crises have demonstrated variable success. Challenges to induced hypothermia include unclear optimal timing, depth, and duration of this therapy. Other strategies to reduce metabolic demand include use of low-dose carbon monoxide and hydrogen disulfide, though the extreme toxicity of these agents limits the therapeutic window for such agents.

Conclusions

Although the restoration of tissue perfusion and oxygen/substrate delivery remains a primary goal in critical illness, alterations in cellular respiration contribute to a bioenergetic imbalance that results in cell—and ultimately—organ dysfunction. As discussed, impaired oxygen delivery can decrease the ability of cells to produce ATP. However, metabolic alterations that affect overall bioenergetic homeostasis may develop, and even persist, irrespective of the state of oxygen delivery. Indeed, it may well be the case that *utilization* of oxygen—or some other metabolic substrate—is of even greater importance to cell survival, organ function, and patient outcomes than normalization of oxygen delivery. Although shock is classically defined as an imbalance between oxygen (and substrate) delivery and demand, ultimately it is the state of cellular respiration rather than circulatory dysfunction that determines outcome from critical illness.

CHAPTER 81

Biology of the Stress Response

Stephen Standage, Jerry J. Zimmerman

PEARLS

- The stress response is a universal, stereotypical, and integrated neurogenic, endocrine, inflammatory, and metabolic systems response with multiple feed forward and feed backward modulation signaling designed to maximize host survival.
- The brain is the paramount organ of the stress response, as it determines what constitutes a stress and what is the appropriate reaction and extent of reaction. Multiple afferent stress signals are integrated at the level of the hypothalamus where the stress response is initiated.
- Excessive or prolonged stress stimuli can precipitate a dysregulated stress response.
- A complicated critical illness course may reflect elements of an ongoing stress response manifested as protein catabolism with poor wound healing, diffuse weakness, and immunosuppression associated with hospital-acquired infections.
- Therapeutic intervention must respect the physiologic alterations necessary to accommodate the stress response. Pursuing "normal" values as physiologic target parameters may ultimately be counterproductive.

Introduction

Human beings demonstrate tremendous adaptability, which has allowed them to inhabit and flourish in all sorts of climates and environments. The resilience of human physiology has permitted the achievement of tremendous feats of endurance and survival under the most inhospitable circumstances. The biological systems that facilitate our detection and response to stresses in our internal and external environments have been crucial to our success as a species. These same systems are at play in the intensive care unit when children confront life-threatening conditions and affect how they respond to both injury and treatment. This chapter discusses the nature and function of the various physiologic systems that constitute the stress

response as it applies to critical illness.

Definitions and Historical Perspectives

Stress may be defined as any force or influence on an organism that perturbs its usual state of equilibrium. Strain is the magnitude of deviation from baseline norms that the organism experiences in response to the inciting stressor. Resiliency is the organism's ability to adapt to or cope with the stresses and strains imposed on it. The process of host adaptation to an environmental, biological, or psychosocial insult is referred to as the stress response.

All life requires a relatively high degree of stability to maintain vital functions. Enzymes perform optimally at specific temperatures and hydrogen ion concentrations. Action potentials are promulgated along cell membranes based on a narrow range of ion concentrations. There are two competing principles relating to stability: homeostasis and allostasis. Homeostasis is the process of achieving stability through maintaining systemic variables within a fairly narrow dynamic range. Allostasis is the process of achieving stability through physiologic or behavioral changes.[1] Whereas normal physiology imposes homeostatic forces on vital functions to maintain constancy within an optimal range, the stress response facilitates a change in physiology to adapt to 85 stressors that would otherwise be fatal. This allostatic response, however, is designed to be temporary so that once the stressor has resolved, the organism can return to its baseline physiologic function. Prolonged exposure to stress or an abnormal stress response induces chronic allostasis, which is pathologic.

To illustrate this concept, the reader may consider a skyscraper built in an earthquake-prone area. Rising high above the earth and bearing thousands of tons of steel, concrete, and glass, the structure normally moves very little. However, in the event of an earthquake the building is engineered to tolerate a significant amount of swaying and rocking to avoid breaking and tumbling to the ground. The attributes of its structural elements that allow it to bend without breaking constitute the resilience of the building, which allow it to accommodate the strain imposed by the stress of the earthquake. Likewise, the stress response in humans provides resilience to adapt to various internal and external stressors without catastrophic physiologic decompensation. Strain is evident in the physiologic changes undertaken in response to stress, which fosters survival.[2]

As a concept, stress was first considered a perturbation of normal intracellular physiology by Claude Bernard in 1892 as part of his classic discussion of constancy of the “environment within” (milieu inte'rieur). At that time he noted that stressors to the cell result in an immediate compensation and equilibrium response and that this property of responding to change was essential for free and independent life. Later in 1932 Walter Cannon actually defined the concept of homeostasis; the stress response was noted to typically occur when homeostasis was disrupted.[3] Clinically the stress response was described as actions facilitating freeze, fright, flight, and fight.

With the benefit of ongoing research in physiology and biochemistry, the stress response was ultimately recognized to be a rather universal, stereotypical, and integrated set of biological activities that respond to both internal and external stimuli.[2] Stressors that were recognized to activate this response included

physiologic, biochemical, emotional, and physical stimuli. In 1936, Selye described chronologic development of the stress response in terms of alarm, resistance, and exhaustion, the latter associated with morbidity and death as opposed to enhanced survival.[4] This dynamic view of the stress response was termed the *general adaption syndrome* and was continued to be viewed as an attempt to reestablish homeostasis and protect the organism during acute stress. Recognized essential clinical aspects of the stress response included adaptive functions such as arousal, vigilance and focused attention, general inhibition of vegetative functions, and increased delivery of both oxygen and nutrients to the brain, heart, and skeletal muscles to facilitate increased metabolic activity. Later, stress response activity was described schematically in terms of a U-shaped graphic, where both insufficient as well as excessive or maladaptive responses might be pathologic.[5]

Subsequently, a perhaps more sophisticated view of the stress response was formulated by McEwen and colleagues employing the concept of allostasis described earlier.[6] In allostasis, the body responds to a particular challenge or stress by adjusting to a new steady state (strain), but it terminates this activity once the stress has stopped. Again, such change may be appropriate and adaptive or, alternatively, maladaptive, particularly if the stress and its associated strain are extreme or prolonged.[1]

A mathematical model of the stress response is depicted as follows[2]:

$$F_n = \int_{t_i}^{t_f} (\rho t_n) \times L(t_n) \times dt$$

Here stress is depicted as a force (F) generated by a stressor that is equal to the host's resilience (ϱ) over time multiplied by the response (L) of the body, which can alternatively be described as strain. Fn, a force generated by a stressor; ϱ, resiliency during evolution of the stress response; L, response of the body; t_n, particular point in time; t_i, time initial; t_f, time final. In real life, strain might be represented by a multiple organ dysfunction score such as PELOD.[7] An individual's resilience is affected by genetic predispositions, comorbid conditions, and environmental influences. A simplified depiction of this integral is the equation that equates the stress force F to the body's resiliency (ϱ) times the change in strain, or $F = \varrho \times \Delta L$.[2]

Stress System Primary Elements

The stress response is mediated by the stress system that reestablishes homeostasis or alternatively maintains stability through change, allostasis. The stress system has an afferent, sensory limb allowing it to detect stress signals as well as an efferent, effector limb, which brings about physiologic responses to address the stressors. Initiation and regulation of the stress response occur in the brain. In this regard the brain is the paramount organ of the stress response, as it determines what constitutes a stress and what is the appropriate reaction and extent of reaction.[8] The brain integrates multiple afferent signals and appraises the degree of threat presented by potential stressors. When the brain perceives stimuli as stress, it triggers allostatic mechanisms through its efferent pathways to maintain physiologic stability in the face of the threat.

[Fig. 81.1](#) depicts the stress system as an integrated network of neurogenic, endocrine, inflammatory, and metabolic subsystems that interact through multiple feed forward and feed backward signaling channels. Ultimately, this system is responsible in eliciting four major responses to stress signals including (1) activation of both the sympathetic and parasympathetic nervous systems; (2) enhanced release of the various counter regulatory hormones, particularly cortisol, and vasopressin with activation of the renin-angiotensin-aldosterone axis; (3) synthesis of both pro- and antiinflammatory mediators; and (4) mobilization of metabolic substrate from physiologic depots to provide energy and molecular building blocks for the highly energetic functions of the stress response. All of these activities are essential for an integrated stress response that maximizes host survival. However, if these activities become dysregulated or prolonged (chronic critical illness), the result may involve evolution from the stress response to the distress response.

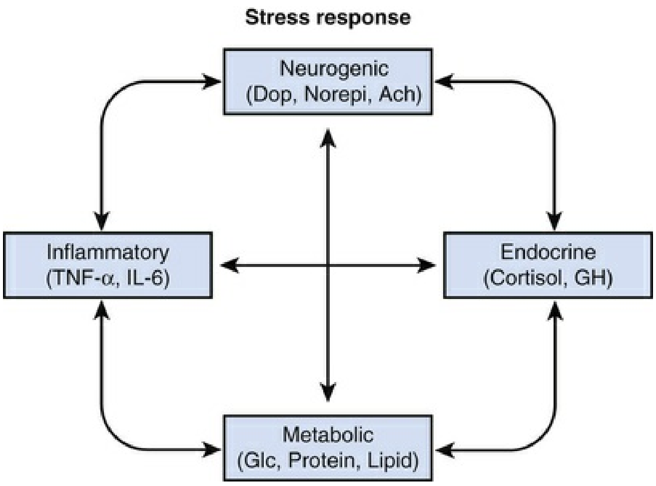

FIG. 81.1 Schematic depiction of the major elements of the stress response. *Ach,* acetyl choline; *Dop,* dopamine; *GH,* growth hormone; *Norepi,* norepinephrine; *TNFα,* tumor necrosis factor alpha; *IL-6,* interleukin-6; *Glc,* glucose.

Stress Response

The effector stress response can be compartmentalized into central, peripheral, and cellular components.[9] The interaction of all these subsystems is coordinated to achieve three primary objectives: (1) maintain perfusion of the heart, brain, and other vital organs; (2) deploy energy resources from body fuel storage depots; (3) optimize adenosine triphosphate (ATP) availability to vital cells and tissues at the expense of nonessential tissues.

Central Activation and Integration

A multitude of signals may activate a stress response.[10,11] Examples of afferent stressors include pain, visual, auditory and olfactory stimuli, and psychologic distress. In critical illness, common stressors include hypoperfusion, hypoxia, tissue injury, and infection. Hypotension is sensed as a decreased stretch of baroreceptors

located in the carotid sinus and aortic arch. Peripheral chemoreceptors in the carotid and aortic bodies sense oxygen levels. Tissue injury and infection are detected by the innate immune system that recognizes both pathogen-associated molecular patterns (PAMPs) as well as host damage-associated molecular patterns (DAMPs) that may occur as a result of direct tissue injury from trauma, critical illness in general, or as collateral damage from inflammatory responses.[12,13] Innate immune cells elaborate cytokines that signal stress to the rest of the body. These cytokines, and various other soluble mediators that provide afferent signaling for the stress response, are transported to the brain and across the blood-brain barrier through fenestrated capillaries as well as by active transport mechanisms. In addition, the vagus nerve facilitates bidirectional communication between the brain and the immune system as well as the various organs that it innervates.[14]

The diencephalon, including the arcuate nucleus, paraventricular nucleus, dorsal vagus complex, catecholamine cell group, and the brain stem, all receive afferent signals activated from both internal as well as external stressors. Multiple afferent stress signals are integrated at the level of the hypothalamus where the stress response is initiated.[10,15,16] Intercommunications between brain stem nuclei, hypothalamus, hippocampus, and limbic systems represent important circuits through which the stress response is coordinated.[8,17]

Peripheral Responses

Efferent signaling from the brain involves descending neuroendocrine and autonomic pathways that ultimately control hemodynamic, immune, and metabolic aspects of the stress response. Activation of the stress system triggers release of the corticotropin-releasing hormone (CRH) from the hypothalamus, which in turn induces release of adrenocorticotropic hormone (ACTH) from the anterior pituitary. Other stimulants of ACTH secretion include vasopressin, catecholamines, angiotensin II, serotonin, vasoactive intestinal peptide, and inflammatory cytokines (IL-1[interleukin-1], IL-2, IL-6, TNFα). ACTH in turn stimulates the adrenal cortex to produce cortisol, which is essential to the stress response to critical illness and injury.[18] Cortisol affects the transcription of approximately 25% of the entire genome,[19] and hence it mediates a wide range of hemodynamic, immunologic, and metabolic actions. A detailed discussion of cortisol metabolism in critical illness is provided in Chapter 85. CRH also induces the secretion of proopiomelanocortin and other opioid peptides—the latter (including β-endorphin) mediate analgesia and provide negative feedback to the stress response.[20]

The parvicellular neurons of the hypothalamus secrete thyrotropin-releasing hormone, which acts on the anterior pituitary gland to release thyroid-stimulating hormone (TSH). Early in critical illness, TSH and T_4 levels increase transiently, but this is associated peripherally with a rapid decline in T_3 levels and an increase in rT_3 levels due to alterations to peripheral conversion of T_4.[21–23] The elevated TSH levels quickly return to the normal range, but T_3 levels remain low, resulting in the nonthyroidal illness or sick-euthyroid syndrome, which is also discussed in more detail in Chapter 85.

Two other hormones from the anterior pituitary are released by the stress response: growth hormone and prolactin. Like most other components of the stress

response, both of these hormones are under control of the hypothalamus. Growth hormone is released from the anterior pituitary in response to hypothalamic growth hormone–releasing hormone (GHRH) secretion. Prolactin release, which facilitates the immune response by augmenting lymphocyte activation, is under tonic inhibition from dopaminergic neurons in the hypothalamus. Its secretion is enhanced with decreased dopaminergic signaling from the hypothalamus. Secretion of both of these hormones is stimulated by activation of the stress response.

Vasopressin release is another early response to stress that is crucial to survival in critical illness.[24,25] The magnocellular neurons of the hypothalamic supraoptic and paraventricular nuclei project their axons through the pituitary stalk and onto the capillary bed of the posterior pituitary gland where they release vasopressin directly into the circulation. Additionally, corticotropin-releasing hormone and vasopressin signaling pathways mutually innervate and stimulate each other.[26] Vasopressin release is stimulated dramatically by decreased arterial blood pressure, but it can also be activated by increased serum osmolality. Vasopressin induces peripheral vasoconstriction by signaling through the V_1 receptor and thus helps to maintain blood pressure. Activation of V_2 receptors by vasopressin in the renal collecting ducts results in the insertion of aquaporin channels into the luminal membrane of the renal tubular epithelial cells. This mechanism facilitates the reabsorption of free water into the vasculature to maintain or restore circulating blood volume, which is particularly important in shock states.

Receiving inputs from the hypothalamus and the limbic system, the autonomic nervous system is also activated in the stress response. The locus ceruleus, located in the posterior area of the rostral pons, is an important center of sympathetic outflow. Within the central nervous system, sympathetic activation results in increased arousal, concentration, and alertness. Additionally, noradrenergic signals originating in the locus ceruleus descend through autonomic efferent pathways to stimulate a peripheral sympathetic response.[10] Simultaneously, a parasympathetic response is initiated to balance the magnitude of the initial proinflammatory stress response. This balancing aspect of the stress response has been termed the *inflammatory reflex*.[27] Increased vagal efferent signaling suppresses peripheral cytokine release through macrophage nicotinic receptors and the cholinergic antiinflammatory pathway.[28]

The peripheral effects of the stress response are seen most quickly with activation of the sympathetic arm of the autonomic nervous system. The heart, blood vessels, bronchioles, and most endocrine cells are richly innervated with adrenergic nerve fibers. Norepinephrine release from sympathetic axon terminals in the adrenal medulla stimulates secretion of epinephrine into the blood. The combination of circulating epinephrine and release of norepinephrine from adrenergic neurons increases heart rate and blood pressure augmenting cardiac output and maintaining perfusion to vital organs.

An important peripheral system that works in concert with the adrenergic and vasopressin responses is the renin-angiotensin-aldosterone system. The primary purpose of this system is to help regulate sodium and water balance in the body. Renin is produced and stored in the juxtaglomerular granular cells of the afferent renal arterioles. Renin release is mediated by three primary control mechanisms: (1) decreased afferent renal arteriole blood pressure, (2) sympathetic stimulation from noradrenergic autonomic input, and (3) signaling from macula densa cells that sense decreased flow rate and sodium composition of the fluid flowing through the

nephron. Renin is an enzyme that cleaves angiotensinogen, a protein produced in the liver, to generate the 10 amino acid polypeptide angiotensin I. Angiotensin I is further cleaved to an 8 amino acid polypeptide, angiotensin II, by the angiotensin-converting enzyme localized predominantly in the pulmonary vascular endothelium. Angiotensin II has several important effects. It is a potent vasoconstrictor and thereby increases blood pressure. Its vasoconstrictor effects also reduce renal blood flow and the glomerular filtration rate, which serves to prevent urinary fluid losses. Angiotensin II directly stimulates proximal tubular sodium reabsorption in the nephron. One of its most important effects, however, is to stimulate secretion of aldosterone from the adrenal cortex. Aldosterone increases sodium reabsorption in the kidneys, predominantly in the distal convoluted tubule, and also facilitates potassium and hydrogen ion secretion. The increased reabsorption of sodium from the nephron pulls water with it into the vascular space, ultimately increasing the intravascular volume without significantly increasing plasma sodium levels.

Counterregulatory hormones mediate important aspects of the stress response. Adrenergic stimulation also triggers the release of glucagon from alpha cells in the pancreatic islets while inhibiting the release of insulin from the beta cells. This effect of the sympathetic response has important metabolic ramifications. Glucagon—in concert with cortisol, growth hormone, and circulating epinephrine—initiates widespread catabolic mechanisms that affect essentially every tissue in the body. The overarching objective of imposing this catabolic state is to provide energetic substrate and molecular building blocks for the highly resource-intensive functions of the stress response.

These counterregulatory hormones stimulate hepatic gluconeogenesis and glycogenolysis and thereby increase blood glucose levels. Peripheral tissues become resistant to the effects of insulin under the influence of glucagon and growth hormone, which leads to critical illness–associated hyperglycemia. This phenomenon, associated with a decrease in the thyroid hormone T_3, may have as its purpose to reduce the metabolism and energy consumption of nonessential tissues, allowing circulating glucose to be used primarily by those cells and tissues directly involved in the immune response and tissue repair.[22]

In adipose tissue, epinephrine and glucagon activate hormone sensitive lipase, which catalyzes the first step in triglyceride hydrolysis and liberates free fatty acids and glycerol into the circulation. Glycerol is utilized as a gluconeogenic substrate in the liver, and the fatty acids are taken up by metabolically active cells to support their function or to provide structural components necessary for cellular growth and division. Leukocytes, for example, undergo rapid clonal expansion in inflammatory states and require significant amounts of lipid substrate both for activation as well as structural components of cell membranes.[29,30]

Skeletal muscle is also significantly affected. Epinephrine, cortisol, and glucagon initiate glycogenolysis in the muscle, but because myocytes lack glucose-6-phosphatase they cannot release glucose into the bloodstream like the liver. Whatever glucose liberated from glycogen that is not utilized for the energetic demands of the muscle itself is converted into lactate and released into the bloodstream. Indeed, significant β-adrenergic stimulation (eg, exogenous epinephrine) can induce the production of lactate even in the presence of adequate oxygen by inhibiting pyruvate decarboxylase, the final step of glycolysis that

converts pyruvate into acetyl-CoA for incorporation in the mitochondrial citric acid cycle.[31] Some tissues, like the myocardium, can use lactate as a primary energy source, but most of the lactate is taken up by the liver and used as gluconeogenic substrate to further increase circulating glucose levels. Protein catabolism in the muscle also releases amino acids into the circulation, which too are used by the liver for gluconeogenesis and for the elaboration of acute phase proteins necessary for the stress response. This protein catabolism is significantly enhanced by cytokine stimulation from the inflammatory response.[32]

Cellular Responses

Mitochondria represent the final common cellular pathway for the stress response,[33] as these organelles are primarily responsible for generating the enormous energy demands necessary to fuel the fight or flight response. However, in addition to respiration, mitochondria are also involved in thermogenesis, lipid metabolism, calcium regulation, intracellular signaling, and initiation of cell silencing pathways. The latter may involve apoptosis or mitochondrial hibernation (metabolic shutdown), either of which may provide an overarching mechanism for multiple organ dysfunction syndrome (see Chapter 112). It is of interest that short-term exposure to stress concentrations of corticosteroids is associated with induction of mitochondrial biogenesis and enzymatic activity, whereas prolonged exposure is associated with respiratory chain dysfunction, increased reactive oxygen species generation, mitochondrial structural abnormalities, apoptosis, and cell death.[33] A detailed discussion of mitochondrial biology related to critical illness may be found in Chapter 80.

Stress Response in Critical Illness

Critical illness reflects the ultimate manifestation of severe stress. Three phases of the stress response may be observed in the intensive care unit:

1. *Acute phase.* During this early time period after exposure to the critical stressor, analogous to the "Golden Hour" of resuscitation, the stress response comprises primarily those rapidly acting mechanisms designed to preserve tissue perfusion and oxygenation. Blood pressure, cardiac output, and intravascular volume are all maintained through adrenergic signaling, vasopressin secretion, and activation of the renin-angiotensin-aldosterone system. The response time in these systems is so rapid because they rely on preformed mediators to bring about their physiologic effects.

2. *Established phase.* As time elapses, the full breadth of the stress response is brought to bear as endocrine and metabolic mechanisms come into play. These are slower to activate because they rely predominantly on neuroendocrine regulation of gene transcription and protein translation. The focus of this phase of the response is to adapt host physiology to preserve vital functions while directing resources toward resolving the inciting stressor. Nonessential systems are deactivated. To achieve their desired ends, these allostatic changes may permit, or even seek, physiologic parameters that are not congruent with baseline homeostasis. For example, cytokines

stimulate the hypothalamic thermostat to increase body temperature. Though abnormal relative to baseline conditions, fever is an important physiologic adaptation that facilitates leukocyte eradication of infectious agents. This ability to adapt to the needs of the circumstances is the physiologic resilience we referred to at the outset of this chapter.

3. *Recovery or repair phase.* When the inciting stressor is removed, the stress response is attenuated, the strain on host systems is relieved, and the body returns incrementally to normal homeostatic parameters.

From a teleologic point of view, the acute stress response is intended to be self-terminating within hours to a few days at most, rather than a prolonged condition persisting weeks or more. Clearly, failure to mount an adequate stress response is associated with worse outcomes. However, excessive or chronic stress compromises the body's allostatic responses and may itself promote pathology.[1] Due to the magnitude and nature of life-threatening conditions, the stress response in critical illness can become dysregulated and prolonged. When this occurs the stress response devolves into the distress response as pathologic results emerge from misdirected or excessive allostatic adaptations. This is observed frequently in the intensive care unit (ICU).

Decreased neurologic function secondary to the inciting disease process itself or iatrogenic sedation precludes appropriate threat appraisal and stress system regulation by the central nervous system. Excessive adrenergic output can directly impair cardiac function.[34,35] The antiinflammatory neurogenic reflex may play a role in the immunoparalysis seen so often after trauma and sepsis.[27,36]

Both very high and low cortisol levels are observed in critically ill children and are associated with increased mortality.[21,22] Elevated levels of cortisol likely contribute to immune dysfunction as well as metabolic dysregulation, whereas insufficient cortisol secretion is associated with cardiovascular collapse. The debate over steroid administration in critical illness has raged for decades and will likely continue for several more.[37] These topics are reviewed in much greater depth in Chapter 85.

The overall tone of the stress system in severe or prolonged critical illness is one of generalized depression. As noted earlier, thyroid hormone levels are suppressed, which may be an adaptive response, to a degree, by allowing energetic resources to be consumed by more vital processes. When taken to an extreme, however, very depressed thyroid levels are associated with mortality.[38,39] Growth hormone and prolactin release surges early in the stress response but drops to very low levels with persistent critical illness resulting in dysregulated metabolism and immunity.[21,22]

Vasopressin is elevated early in the acute phase of shock states, but it rapidly declines and remains quite low through prolonged critical illness.[24,40] Vasopressin deficiency has been observed among children treated with cardiopulmonary bypass.[41] In septic shock, regulation of vasopressin is characterized by decreased plasma concentrations, unaltered clearance, depleted neurohypophyseal vesicles, and altered osmolar signaling.[42] Likewise the renin-angiotensin-aldosterone system can be dysregulated in critical illness. Elevated renin and angiotensin are observed in sepsis and correlate with measures of microvascular dysfunction and organ system failure.[43] In a subset of critically ill patients, however, aldosterone levels are inappropriately low despite elevated plasma renin activity.[44–46] Mineralocorticoid

deficiency may therefore contribute to the hyponatremia sometimes observed in pediatric intensive care unit (PICU) patients.

Significant metabolic dysregulation can be seen with severe and persistent stress responses. The combined effect of increased glucose production and peripheral insulin resistance can result in extremely elevated blood sugar levels, which correlate with organ system dysfunction and survival.[47–49] Intense hypercytokinemia and adrenergic stimulation both mobilize lipid and amino acid substrate from adipose tissue and skeletal muscle, which can result in hypertriglyceridemia and severe muscle wasting.[50,51,32] The clinical significance of elevated serum triglyceride levels is uncertain, but muscle wasting leads to critical illness–related weakness and prolonged mechanical ventilation with all of their comorbidities.[52]

Analogous to inflammation, stress is beneficial acutely but when prolonged may generate collateral damage. Complicated or prolonged critical illness may represent a stress-related decompensation syndrome.[2] A complicated ICU course may reflect elements of an ongoing stress response manifested as protein catabolism with poor wound healing and diffuse weakness and immunosuppression associated with hospital-acquired infections, all of this reflecting a persistent inflammation immunosuppression catabolism syndrome (PICS).[53] When stress evolves into distress, allostatic overload occurs resulting in mitochondrial hibernation as an antecedent of metabolic shutdown and widespread energy failure associated with multiple organ dysfunction syndrome (MODS).[54] Maladaptive response to stress can outlast the actual stress phase by months or even years, and chronic stress can lead to the development of the metabolic syndrome long after discharge from the PICU.[55]

Recommendations and Conclusions

An understanding of the stress response should influence how we care for children in the PICU. Because pathophysiology can change rapidly in critical illness and varies along the continuum from injury to resolution, we need to adapt our clinical posture to fluctuating physiologic parameters in the different phases of the stress response:

1. *Acute phase.* In this “Golden Hour” period, emphasis is directed at avoiding hypoxemia and ischemia. Attention must also be paid to removing the inciting stressor that has precipitated the stress response as quickly as possible. For example, in infectious causes of critical illness, achieving early source control is paramount. Likewise, aggressive interventions to stop seizures in status epilepticus or to relieve bronchoconstriction in severe asthma are crucial. The longer the stimulus persists, the more intense and prolonged the stress response it elicits.

2. *Established phase.* During this interval, clinicians should focus on permissive treatment that respects the stress response and avoids iatrogenic injury, recognizing that many ICU interventions can exacerbate stress system dysregulation (vasoactive infusions, systemic steroids, etc.). Healthy physiologic values routinely targeted in the critically ill may not be appropriate in light of the adaptations necessary for the stress response. The therapeutic implication here is that most of the acute endocrine and metabolic responses are likely to be adaptive and thus should probably not be aggressively treated.[21] In many situations providing less intervention may provide

greater long-term benefit.[56]

3. *Recovery or repair phase.* In this phase, clinicians refocus on targeting normal physiologic values. Here the environment of the ICU plays a key role in terms of avoiding prolongation or reinitiation of an acute stress response.

In addition to providing critical care interventions targeted at removing the primary pathophysiologic stressors, the multidisciplinary care team can optimize long-term outcomes by implementing interventions to de-stress their critically ill patients: avoiding supraphysiologic resuscitation; facilitating sleep; reestablishing circadian rhythms; decreasing noise levels; avoiding pain, anxiety, and delirium; promoting early mobilization; providing natural light; and restoring entitlement.

CHAPTER 82

Inborn Errors of Metabolism

Cary O. Harding

PEARLS

- Unexpected and unexplained clinical deterioration in a previously healthy infant or child is an important clue to the presence of an inborn error of metabolism (IEM).
- Loss of previously attained developmental milestones during childhood is an important clue to the presence of a neurodegenerative disorder such as lysosomal storage disease.
- Blood glucose less than 40 mg/dL is distinctly unusual after the first 24 hours of life, particularly in infants who have started feeding, and should be thoroughly investigated.
- Laboratory evaluation for inborn error of metabolism should be undertaken in any child with a suggestive clinical history regardless of the results of newborn screening. A normal newborn screen, although perhaps reassuring, does not rule out the possibility of an IEM.
- With catastrophic illness in a previously well child without signs of any particular IEM, the "shotgun" diagnostic evaluation should minimally include plasma amino acid analysis, plasma acylcarnitine profile, urine organic acid analysis by gas chromatography-mass spectrometry, and urine-reducing substances.

Metabolism can be defined as the sum of all biochemical processes that convert food to smaller molecules and energy for the purposes of structure and function. An inborn error of metabolism (IEM) is an inherited deficiency of any critical step in metabolism. Although genetic deficiency of catalytic enzymes in intermediary metabolic pathways is the classic paradigm for IEM, the pathophysiology of metabolic disorders may involve abnormalities of any number of cellular processes, including transmembrane transport, cell signaling, cell differentiation and development, energy production, and others. Many IEMs are individually rare, although a few, including phenylketonuria (PKU)[1] and medium-chain acyl-

coenzyme A (acyl-CoA) dehydrogenase deficiency (MCADD),[2] a defect in fatty acid oxidation, exhibit a population incidence approaching 1 : 10,000 live births. Specific IEMs may be more common in certain ethnic groups with a history of relative reproductive isolation. Collectively, the population incidence of all IEMs may approach 1 : 1500 live births, depending on how broadly IEM is defined. Many IEMs are associated with catastrophic illness necessitating advanced life support. Although IEM may present rarely within the professional lifetime of the average medical practitioner, critically ill children with IEM will not be uncommon visitors to the pediatric intensive care unit, especially in a tertiary care center.

Other published textbooks on the diagnosis and treatment of IEM provide an exhaustive list of known disorders.[3,4] Rather than recapitulate an encyclopedia of possible diseases, this chapter presents a diagnostic rationale based on specific clinical symptom complexes that are likely to occur in the critically ill child. Algorithms for the differential diagnosis of specific clinical scenarios are given in support of this rationale. Symptoms often begin during early infancy in the biochemically most severe IEM; naturally, these IEMs with neonatal onset are the focus of the discussion in this chapter. However, “milder” or late-onset variants of virtually every IEM have been described with onset of symptoms occurring at all ages, even during adulthood. Some IEMs uniformly present after the neonatal period; age of symptom onset (late infancy, childhood, or adulthood) often is an important clue to the specific diagnosis. The clinical presentation, diagnostic workup, and treatment of neonatal onset disorders provide a paradigm for the evaluation and management of possible IEM in a child of any age.

Pathophysiology of Inborn Errors of Metabolism

Under the classic paradigm, an IEM is associated with deficiency of a specific protein, often a catalytic enzyme, involved in a critical metabolic pathway (Fig. 82.1). This deficiency leads to a block in the pathway and the accumulation of the enzyme substrate. In this model, three distinct pathogenic mechanisms are possible proximate causes of the symptoms associated with an IEM. The specific pathogenic mechanism involved in any given IEM dictates the appropriate treatment strategy. First, accumulation of the substrate may lead to toxic effects at very high levels; successful therapy requires effective elimination of the substrate or a method to block its toxic effects. An example for this mechanism is PKU, in which elevated phenylalanine levels adversely affect neuronal development, and the reduction of tissue phenylalanine content through dietary phenylalanine restriction largely prevents the major clinical features of PKU.[5] Second, deficiency of the reaction product, should it be a critically important metabolite, may lead to disease. Supplementation with the essential metabolite, if possible, may cure the disease. Biotin is a required cofactor for four distinct carboxylase enzymes. Deficiency of free biotin develops in the face of genetic biotinidase deficiency and leads to symptoms of multiple carboxylase deficiency. Supplementation with oral biotin completely prevents the clinical manifestations of biotinidase deficiency.[6] The final pathogenic mechanism involves the conversion of the enzyme substrate, through normally quiescent alternative pathways, to toxic secondary metabolites. Elimination or

decreased production of these secondary metabolites may improve disease symptoms. For example, tyrosinemia type I (fumarylacetoacetate hydrolase [FAH] deficiency) is associated with recurrent attacks of abdominal pain and paresthesias reminiscent of acute intermittent porphyria. The accumulating substrate, fumarylacetoacetic acid, is converted through secondary pathways to succinylacetone, and succinylacetone in turn inhibits the heme synthetic pathway and causes porphyria-like symptoms. Pharmacologic inhibition of the tyrosine catabolic pathway proximal to the block at FAH decreases the production of fumarylacetoacetic acid and succinylacetone and alleviates the pathology associated with these toxic compounds.[7]

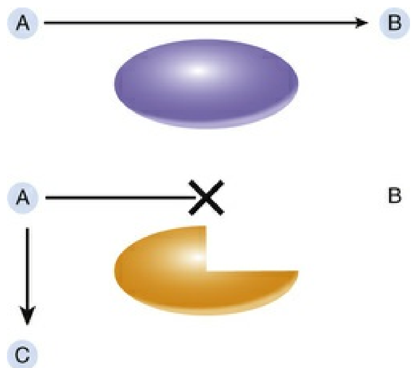

FIG. 82.1 Inborn error of metabolism paradigm. Normally, in a given step of intermediate metabolism with intact enzymatic activity, the substrate A is efficiently converted to the product B. In an inborn error of metabolism, a deficiency of enzyme activity may lead to excessive accumulation of the substrate; critical deficiency of the product; or production of an alternative, potentially toxic metabolite C through normally quiescent pathways.

Inheritance of Inborn Errors of Metabolism

IEMs are heritable disorders. The majority of diseases are inherited in an autosomal recessive pattern, yielding a 25% recurrence risk in future offspring. The gene defects associated with several IEMs are located on the X chromosome. These IEMs, such as ornithine transcarbamoylase deficiency and glycerol kinase deficiency, are inherited in an X-linked pattern. These IEMs are most severe in males, but carrier females may be symptomatic, although usually with less severe or late-onset disease as a result of skewed X chromosome inactivation. Mutations for several mitochondrial disorders are found on mitochondrial deoxyribonucleic acid (mtDNA). Because mtDNA is exclusively passed from mothers to their offspring, these IEMs exhibit a maternal inheritance pattern but often with variable penetrance and expressivity. Prenatal diagnosis is possible for many IEMs. In addition to allowing for appropriate medical therapy, the timely diagnosis of an IEM in a sick infant or child is important for genetic counseling purposes.

Signs and Symptoms of Inborn Errors of

Metabolism

Clinical signs and symptoms frequently associated with IEM are listed in Table 82.1. The symptom repertoire of the critically ill infant is limited, and the clinical presentation of metabolic disorders often is nonspecific. It is for this reason that the diagnosis of an IEM may be easily missed. To maintain maximum diagnostic sensitivity for IEM, the clinician must maintain a high level of suspicion and be willing to initiate screening metabolic laboratory studies with little provocation (Box 82.1). As was true for appendectomies in the era prior to the advent of ultrasound-based diagnosis of appendicitis, a certain number of nondiagnostic metabolic laboratory workups in sick children must be performed to ensure ascertainment of individuals with inherited metabolic disorders. In particular, IEM should be a strong diagnostic consideration in any neonate who has become catastrophically ill following a period of normalcy. This presentation may be clinically indistinguishable from bacterial or viral sepsis, and the nonspecific supportive therapy provided to potentially septic infants (fluid and glucose administration) may alleviate the symptoms and mask the presence of an IEM. Diagnostic metabolic laboratory studies are most likely to provide definitive information if performed on clinical samples obtained at initial presentation and before any therapy is initiated. Failure to obtain the necessary specimens at this time may miss an important diagnostic window of opportunity. Many children with IEM have been saved initially by intensive but nonspecific treatment but then suffered clinical relapse or even death in the absence of the correct diagnosis. Certainly, the possibility of an IEM should be considered in any child for whom the clinical picture suggests sepsis, but the laboratory evaluation for sepsis is negative. Unfortunately, bacterial sepsis is often a complicating factor in critically ill children with IEM. For example, *Escherichia coli* infection (including pyelonephritis, bacteremia, or meningitis) is frequently detected at presentation in infants with galactosemia. The astute clinician remains ever vigilant for the signs and symptoms that may suggest an inherited metabolic disorder.

TABLE 82.1

Signs and Symptoms of Inborn Errors of Metabolism

Acute illness after period of normal behavior and feeding (hours to weeks)
Recurrent decompensation with fasting, intercurrent illness, or specific food ingestion
Unusual body odor
Persistent or recurrent vomiting
Failure to thrive
Apnea or tachypnea
Jaundice
Hepatomegaly or liver dysfunction
Lethargy or coma
Sepsis
Unexplained hemorrhage or strokes
Developmental delay with unknown etiology
Developmental regression
Seizures, especially if seizures are intractable
Hypotonia
Chronic movement disorder (ataxia, dystonia, choreoathetosis)
Family history of unexplained death or current illness in siblings
Parental consanguinity

Box 82.1

Screening Metabolic Laboratory Studies for Children With Suspected Inborn Errors of Metabolism

- Plasma amino acid analysis

Minimum 2 mL blood in a heparin tube

- Plasma acylcarnitine profile

Minimum 2 mL blood in a heparin tube

- Urine organic acid analysis
- Urine screening—reducing substances, qualitative mucopolysaccharide screening

Minimum 10 mL urine

Recurrent episodes of vomiting and dehydration in response to fasting or intercurrent illness are an important clue to IEM in older infants and children. Feeding difficulties and failure to thrive are common chronic complications. Children with unexplained hypotonia, developmental delay, or movement disorder should be evaluated for possible IEM. Inherited neurodegenerative disorders, such as the lysosomal storage diseases, stereotypically cause developmental regression, specifically loss of previously attained developmental milestones. Several IEMs are associated with major physical anomalies (Table 82.2). When present, these anomalies are exceedingly valuable in suggesting a specific diagnosis and directing the diagnostic evaluation. More commonly, the child with IEM is morphologically normal, and the presenting symptoms are nonspecific. The clinician must then rely on screening laboratory tests to evaluate the potential for IEM.

TABLE 82.2

Physical Anomalies Associated with Inborn Errors of Metabolism

Dysmorphic facial features	Peroxisomal disorders Glutaric aciduria type II Smith-Lemli-Opitz syndrome Menkes syndrome Lysosomal storage disorders
Structural brain anomalies	Glutaric aciduria type II (cortical cysts) Pyruvate dehydrogenase deficiency (cortical cysts, agenesis of the corpus callosum) Glycosylation disorders (cerebellar agenesis)
Macrocephaly	Glutaric aciduria type I (with subdural effusions) Canavan disease Alexander disease
Cataracts	Galactosemia Peroxisomal disorders Mitochondrial disorders Lowe syndrome
Lens dislocation	Homocystinuria Sulfite oxidase deficiency Molybdenum cofactor deficiency

Pigmentary retinopathy	Peroxisomal disorders Lysosomal storage disorders (cherry red spots) Long chain 3-hydroxyacyl-CoA dehydrogenase deficiency
Renal cysts	Glutaric aciduria type II Peroxisomal disorders Mitochondrial disorders
Ambiguous genitalia	Congenital adrenal hyperplasia Smith-Lemli-Opitz syndrome
Skeletal abnormalities	Menkes disease Homocystinuria Peroxisomal disorders Lysosomal storage diseases
Hair or skin abnormalities	Menkes disease Holocarboxylase synthetase deficiency Biotinidase deficiency Argininosuccinic aciduria Phenylketonuria

Laboratory Evaluation of Suspected Inborn Errors of Metabolism

Abnormal results of routine laboratory studies may provide clues to the presence and type of IEM (Table 82.3). Highly informative but sometimes subtle laboratory abnormalities are often overlooked, especially in a busy intensive care unit or hospital ward. For instance, a clinically relevant newborn screening result may have been sent to the primary care provider or birth hospital but not efficiently communicated to the intensive care unit in a different hospital, to which the now critically ill infant has been admitted. It is imperative to verify the infant's screening results with the primary care provider or newborn screening laboratory. Calculation of the anion gap, another example of a routine and highly informative result, is key to the differential diagnosis of metabolic acidosis (see also Chapter 76). The absence of urine ketones in hypoglycemic children older than 2 weeks strongly suggests impaired ketogenesis as a consequence of either hyperinsulinism or fatty acid oxidation disorder. On the other hand, fatty acid oxidation and ketogenesis are incompletely developed in neonates. The presence of ketones in urine of infants younger than 2 weeks is unusual, even during fasting or hypoglycemia, and suggests the presence of an unusual ketoacid, such as those excreted in maple syrup disease or the organic acidemias. Ketoacids, organic acids, and sugars such as galactose or fructose increase urine specific gravity. Urine specific gravity >1.020 in any neonate or in well-hydrated older children suggests the unexpected presence of an osmotically active substance. Routine urinalysis at many hospitals may not include use of the Clinitest to detect reducing substances. Urine Chemstrips utilize a colorimetric glucose oxidase-based method to specifically detect glucose. This test does not react with any other sugar (galactose or fructose). However, some bedside glucose monitoring systems do react with galactose or fructose; inappropriately elevated capillary blood “glucose” accompanied by a normal venous glucose as measured by chemistry analyzer suggests the presence of a sugar other than glucose in the blood. A comatose infant with a blood urea nitrogen (BUN) level below the limits of detection may have an inherited defect in the urea cycle. Blood ammonia measurement is crucial to confirming that suspicion. Failure to check the blood ammonia level has caused missed diagnoses, failure to appropriately treat hyperammonemia, and morbidity and mortality in comatose infants with urea cycle

disorders or organic acidemias. Finally, bacterial sepsis and meningitis are more common causes of severe lethargy and coma in infants than is IEM, but bacterial infection may also be a complicating feature in severely ill infants with IEM. Infants with galactosemia, for example, are particularly prone to pyelonephritis, bacteremia, sepsis, or meningitis, often with *E. coli*, as noted previously. Antibiotic therapy without diagnosis and specific treatment of the underlying disorder may be useful in the short term but does not mitigate long-term IEM-specific effects.

TABLE 82.3

Initial Laboratory Evaluation of Suspected Inborn Errors of Metabolism

Laboratory Test	Abnormality	Disorder
Complete blood count	Neutropenia	Organic acidemias Glycogenosis type 1b
	Macrocytic anemia	Cobalamin processing defects
	Pancytopenia	Congenital lactic acidoses
Serum electrolytes	Metabolic acidosis	Glycogenoses Organic acidemias FAO disorders MSUD Congenital lactic acidoses
Blood gas	Metabolic acidosis	Same as above
	Metabolic alkalosis	Urea cycle disorders
Blood urea nitrogen (BUN)	Low or undetectable BUN (with hyperammonemia)	Urea cycle disorders
Transaminases (ALT, AST)	Liver dysfunction	Galactosemia Fructosemia Tyrosinemia Alpha-1-antitrypsin deficiency FAO disorders Organic acidemias Congenital lactic acidoses Congenital disorders of glycosylation
Total and direct bilirubin	Hyperbilirubinemia	Galactosemia Fructosemia Tyrosinemia Alpha-1-antitrypsin deficiency Congenital lactic acidoses
Serum uric acid	Hyperuricemia	Glycogenoses Purine disorders
Blood ammonia	Hyperammonemia	Urea cycle disorders FAO disorders Organic acidemias
Blood lactate	Lactic acidemia	Congenital lactic acidoses Glycogenoses Fructosemia Gluconeogenesis disorders
Urinalysis	Unusual odor	PKU, MSUD, organic acidemias
Odor Color pH Specific gravity Ketones Reducing substances	Inappropriately high specific gravity due to metabolites	Organic acidemias, galactosemia, fructosemia
	Ketosis	MSUD, organic acidemias
	Positive reducing substances	Galactosemia, fructosemia

FAO, fatty acid oxidation; *MSUD*, maple syrup urine disease; *PKU*, phenylketonuria.

Suspicion of an IEM based on clinical and routine laboratory findings should initiate specialized biochemical testing (Table 82.4). In the case of severely ill infants or when the clinical suspicion of IEM is very high, consultation with a biochemical geneticist, even if only by phone, is strongly advised to help direct the laboratory investigation and initial therapy. When the clinical presentation is nonspecific—that is, catastrophic illness in a previously well child without signs of any particular IEM

—the “shotgun” diagnostic evaluation should minimally include plasma amino acid analysis, urine organic acid analysis by gas chromatography-mass spectrometry, and a so-called urine metabolic screen. The battery of qualitative assays included in a urine metabolic screen differs among laboratories, and the ordering clinician should be aware of which tests and disorders are included in the repertoire of the diagnostic laboratory chosen. Furthermore, although diagnostic laboratories in the United States must meet Clinical Laboratory Improvement Amendment (CLIA) requirements and often are accredited by the College of American Pathologists (CAP), the testing methodologies used, the quality of diagnostic testing for IEM, and more problematically the availability of laboratory-associated consultants with experience in the diagnosis and treatment of IEM vary widely among laboratories. Although the ability of clinicians to direct clinical specimens toward specific diagnostic laboratories may be inhibited by contractual arrangements between the hospital and large referral laboratories, the critically ill patient is best served by diagnostic evaluation carried out in a timely manner by an experienced biochemical genetics laboratory, with laboratory staff available by phone for expert consultation on interpretation of test results.

TABLE 82.4

Biochemical Genetic Laboratory Studies

Specimen	Test	Disorder
Blood	Plasma amino acid analysis	Aminoacidopathies
	Plasma carnitine	Organic acidemias FAO disorders
	Plasma acylcarnitine profile	Organic acidemias FAO disorders
	Serum transferrin electrophoresis	Congenital disorders of glycosylation
Urine	Metabolic screen	
	Ketones	Organic acidemias
	Reducing substances	Galactosemia, fructosemia
	Mucopolysaccharide screen	Mucopolysaccharidoses
	Organic acid analysis	Organic acidemias FAO disorders
	Acylglycine profile	Organic acidemias FAO disorders
	Quantitative mucopolysaccharide measurement and electrophoresis	Mucopolysaccharidoses
	Qualitative sulfites (Sulfitest) or quantitative sulfocysteine	Sulfite oxidase deficiency Molybdenum cofactor deficiency
	Quantitative succinylacetone	Tyrosinemia type 1
	Quantitative purines	Purine synthesis disorders

FAO, fatty acid oxidation.

The specific clinical presentation or specific screening laboratory findings may direct the intensivist or biochemical geneticist to order other more specialized metabolic tests (see Table 82.4). These analyses may provide diagnostic confirmation for specific disorders and supportive evidence alone for others. For several IEMs, confirmation of diagnosis may require enzyme activity analysis in tissue (red blood cells, lymphocytes, cultured skin fibroblasts, liver, or skeletal muscle depending on the specific disorder in question) or molecular DNA testing for a specific gene defect. In general, these tertiary tests, which are often difficult, labor intensive, and expensive, should be ordered following consultation with a biochemical geneticist. In some instances, confirmatory diagnostic biochemical or molecular tests are available only through specialized research laboratories. Molecular DNA analysis

has become a prevalent and powerful weapon in the arsenal of available diagnostic tools. Whole exome sequencing—that is, DNA sequencing of all regions of the genome known to code functional proteins, using novel high throughput DNA sequencing platforms—has proved utility in the diagnosis of complex phenotypes.[8] Biochemical testing, which is more rapidly accomplished than DNA sequencing in most clinical laboratories and which is necessary to confirm the pathogenicity of sequence variants detected by molecular DNA analysis, remains vital to the process of disease diagnosis and treatment management.

Postmortem Evaluation of a Child With Suspected Inborn Errors of Metabolism

Some IEMs, particularly those exacerbated by fasting, may present as sudden infant death. For many IEMs, acute metabolic compensation may be rapid and lethal despite intensive medical intervention. The time after clinical presentation but prior to death may be insufficient to execute an adequate metabolic evaluation. Disease diagnosis is still possible postmortem and is important for fully understanding the cause of death and determining recurrence risk in the family. A protocol for postmortem evaluation of an infant or child with suspected IEM is provided in Table 82.5. Many of the biochemical genetic analyses recommended for acutely ill children are still valid on postmortem specimens. Valuable information may be learned from amino acid, carnitine, and acylcarnitine analyses in blood and from metabolic screening and organic acid analysis in urine (Box 82.2). However, collection of blood and urine may not be possible postmortem, especially if the autopsy is performed many hours after death. In these instances, metabolic testing may be obtained on alternative specimens such as vitreous humor or bile. In the event that screening biochemical studies suggest a specific diagnosis, disease confirmation by enzyme analysis in tissue is highly desirable. Many enzymes can be assayed in cultured fibroblasts; viable fibroblasts may be cultured from skin or Achilles tendon samples obtained as late as 24 hours after death. Biopsies of other organs may be necessary for analysis of certain other enzymes. Muscle, liver, and kidney specimens may be obtained postmortem for enzymatic analysis, but most enzymatic activities in solid organs deteriorate rapidly following death. Collection of specimens as soon as possible after death is critical for valid enzyme analyses.

TABLE 82.5

Postmortem Biochemical Genetic Evaluation

To be performed on any deceased infant <1 year for which the cause of death is not apparent or any child with suspected IEM. Analyses are most reliable if obtained within 6 hours after death.
1. Contact newborn screening laboratory for results of neonatal screening.
2. Obtain a 3-mm punch biopsy of skin or Achilles tendon for fibroblast culture.
A. Prepare skin with chlorhexidine (Hibiclens) or alcohol. Do not use Betadine because it may inhibit fibroblast growth.
B. Use sterile technique.
C. Store biopsy specimen in sterile RPMI culture media (if available) at room temperature. May be stored in sterile nonbacteriostatic saline for up to 24 hours prior to culture if culture media are not readily available.
D. Send to cytogenetics or biochemical genetics laboratory for culture, possible enzyme analyses, and frozen storage.
3. Collect blood via cardiac puncture (~5 ml per tube).
A. One red top tube at room temperature. Collect and store serum at −70°C.
—I. Comprehensive metabolic panel (potassium, lipids, uric acid may not be accurate postmortem)
—II. If hypoglycemic, insulin, growth hormone, and cortisol levels

B. One green top (sodium heparin) at room temperature. Collect and store plasma at −70°C.
—I. Plasma amino acid analysis
—II. Plasma carnitine levels
—III. Plasma acylcarnitine profile
C. One green top (sodium heparin) at room temperature for cytogenetic (karyotype) analysis.
D. If storage disorder suspected, one green top (sodium heparin) at 4°C (wet ice) for leukocyte isolation and diagnostic enzyme analyses.
E. One lavender top (EDTA) tube at room temperature for complete blood count.
F. One yellow top (ACD) tube for DNA isolation and possible mutation analysis.
G. If infant <1 year, spot whole blood onto newborn screening filter paper card for repeat screen.
H. Blood lactate and ammonia may not be accurate postmortem.
4. Collect urine (10–20 mL) by suprapubic tap or by swabbing the bladder interior with cotton swab.
A. Urinalysis
B. Urine-reducing substances
C. Urine organic acid analysis
D. If storage disorder suspected, quantitative urine mucopolysaccharide and oligosaccharide analysis
5. If urine is unobtainable, organic acid analysis may be performed on vitreous humor collected by needle aspiration from an eye. Freeze vitreous humor at −70°C
6. If blood is unobtainable, collect bile (2–3 mL) via puncture of the gallbladder for acylcarnitine profile. Store at −20°C.
7. Collect several biopsies (2 g each) from skeletal muscle, cardiac muscle, kidney, and liver.
A. For routine histology, biopsies should be submitted fresh to the pathology laboratory.
B. For enzyme analyses, biopsies should be wrapped in aluminum foil, placed in a labeled small specimen container, and immediately frozen in liquid nitrogen. Store at −70°C.

Emergency Treatment of Children With Suspected Inborn Errors of Metabolism

Laboratory investigation of suspected IEM may require several days to complete, given that the biochemical genetics laboratory may be physically remote from the treating hospital and many of the tests involve complex specimen preparation and analysis. A general approach to emergency treatment of children with suspected IEM while awaiting diagnostic studies is outlined in Table 82.6. For many IEMs associated with acute catastrophic illness, elimination of the offending metabolite is the key to therapy. Immediate cessation of oral feedings, to stop protein or fat intake, will begin to limit toxin production in disorders of amino acid or fatty acid metabolism. Adequate energy intake as carbohydrate must be supplied, usually parenterally, until a specific diagnosis and definitive treatment plan are available. Dextrose infusion at a high rate suppresses catabolism and reduces the consumption of endogenous protein or fatty acid stores. In extremely recalcitrant cases, insulin infusion drives anabolism and further decreases toxin production. Acute metabolic decompensation in some IEMs (eg, maple syrup disease) is associated with mild peripheral insulin resistance. Insulin administration (often as little as 0.01–0.05 units/kg/hour given by continuous intravenous [IV] infusion or subcutaneous bolus injection) overcomes this resistance and has an immediate impact on metabolic control. Some clinicians also use anabolic agents such as growth hormone or testosterone to acutely suppress protein and fat catabolism. In certain types of congenital lactic acidosis, particularly defects of pyruvate metabolism, carbohydrate infusion worsens lactic acidosis. Replacement of some carbohydrate with fat as an intralipid infusion may partly reduce blood lactate levels, but infants with this degree of sensitivity to glucose infusion often are difficult to treat and suffer high mortality. Severe hyperammonemia that does not respond to dietary protein restriction and dextrose infusion must be treated by hemodialysis. Ammonia clearance with exchange transfusion or peritoneal dialysis is insufficient to adequately decrease blood ammonia levels. If the results of specialized biochemical genetic diagnostic tests are expected within 2 to 3 days, then parenteral dextrose infusion alone should be adequate to maintain nutrition until a more definitive treatment plan is available. Beyond 3 days, developing essential amino acid and fatty acid deficiencies may induce catabolism of endogenous protein and fat. To prevent

this occurrence, enteral or parenteral nutrition with minimal amounts of protein (0.5 g/kg body weight/day) and lipid (20% of total energy intake) should be considered. Empiric administration of cofactors such as the B vitamins is not harmful and may improve metabolite clearance, particularly in disorders caused by deficiency of enzymes that require specific cofactors. Carnitine is required for transport of long-chain fatty acids across the mitochondrial membrane and serves a secondary role in the disposal of excess and potentially toxic acyl-CoA species. Secondary carnitine deficiency is commonly associated with acute metabolic decompensation in organic acidemias and fatty acid oxidation defects. L-Carnitine administration prevents secondary carnitine deficiency and may improve clearance of toxic metabolites; it is lifesaving in specific inherited dilated cardiomyopathies.

TABLE 82.6

Emergency Treatment of Suspected Inborn Error of Metabolism

Goal	Action
Suppress toxic metabolite production	Discontinue oral feedings
Correct fluid imbalance and electrolyte abnormalities	Appropriate intravenous fluid management
Correct hypoglycemia	Intravenous dextrose-containing fluid infusion
Correct metabolic acidosis	Intravenous hydration if pH >7.2 Add IV bicarbonate if pH <7.2 Sodium bicarbonate (1 mEq/ml solution), 1 mEq/kg IV push at <1 mEq/min. May repeat ×3 until pH >7.2; maximum dose 7 mEq/kg/24 hours
Correct hyperammonemia	Suppress protein catabolism Hemodialysis
Treat infection	Appropriate infectious disease laboratory evaluation and antibiotic therapy
Suppress protein and lipid catabolism	Infuse D_{10}1/2NS at 1.5–2× maintenance rate Add insulin infusion if hyperglycemic If severe, unrelenting acidosis, consider growth hormone or testosterone therapy to promote anabolism.
Empiric cofactor administration	L-carnitine, 25–50 mg/kg/every 6 hours IV if organic acidemia suspected or cardiomyopathy present. B vitamin complex, 100 mg each vitamin every day Vitamin B_{12}, 1 mg IM ×1 if macrocytic anemia
Maintain nutritional status (if without enteral feeds ×2 days and without diagnosis of a specific IEM)	Enteral feeds or parenteral hyperalimentation to include the following: Protein, 0.5 g/kg/day only Lipid, 20% of total energy intake Carbohydrate to provide at least the minimum necessary energy intake

Classification of Inborn Errors of Metabolism by Clinical Presentation

As mentioned previously, the clinical presentation of IEM in neonates provides a paradigm for the suspicion and evaluation of potential IEM at all ages. The classification outlined here is adapted and expanded to include late-onset disorders from a neonatal IEM classification system first described by Jean-Marie Saudubray and colleagues.[4,9]

IEM can be classified into one of three groups by pathogenic mechanism. In group 1 IEMs, the production or catabolism of complex molecules is disturbed. The lysosomal storage and peroxisomal disorders are included in this group. The

symptoms of these disorders include permanent and progressive somatic and neurologic abnormalities that develop in utero, are often clinically apparent at birth, and are unaffected by food intake. This group is often distinguished by the presence of somatic abnormalities such as dysmorphic features or hepatosplenomegaly. Typical clinical features, potential neonatal and late-onset diagnoses, and confirmatory diagnostic tests are listed in Table 82.7.

TABLE 82.7

Features of Group 1 Inborn Errors of Metabolism

Clinical Features	Laboratory Findings	Possible Diagnoses	Specialized Diagnostic Tests
Hepatosplenomegaly Coarse facies Macroglossia Fetal hydrops Macular cherry red spots Bone changes Hypotonia or hypertonia Chronic rhinorrhea Failure to thrive	Liver dysfunction No acidosis Normal ammonia Normal glucose	Neonatal onset GM1 gangliosidosis I cell disease Sialidosis Galactosialidosis Niemann-Pick type A MPS VII CDG Later onset Tay-Sachs disease Krabbe disease Other MPS syndromes Niemann-Pick B or C	Urine mucopolysaccharides Urine oligosaccharides Serum transferrin electrophoresis Enzyme analysis in molecular DNA analysis serum, lymphocytes, or fibroblasts
Hepatomegaly Dysmorphic facies Severe hypotonia Large anterior fontanelle Seizures Epiphyseal calcific stippling on x-ray	Liver dysfunction No acidosis Normal ammonia Normal glucose Adrenal insufficiency	Peroxisomal disorders Zellweger syndrome Neonatal adrenoleukodystrophy Others	Plasma very-long-chain fatty acid analysis Functional and genetic analysis of fibroblasts Molecular DNA analysis

CDG, congenital disorders of glycosylation; *MPS*, mucopolysaccharidosis; *MPS VII*, Sly syndrome.

In group 2 IEMs, the symptoms are caused by defects in the production or utilization of energy. This group includes the congenital lactic acidoses, glycogenoses, gluconeogenic defects, and fatty acid oxidation disorders. In group 3 IEMs, clinical symptoms are caused by progressive intoxication in a previously well infant because of accumulation of toxic metabolites proximal to a metabolic block. Often, neonatal onset IEM in groups 2 and 3 can be distinguished by the time of clinical onset relative to birth. The symptoms of a block in energy production or utilization (group 2) may present within hours after birth, whereas symptoms of intoxication (group 3) develop over the first week of life with increasing food intake and accumulation of toxic metabolites. However, variants of many of these disorders may not become clinically apparent for several months or even years after birth.

Group 2 Inborn Errors of Metabolism

Systemic or tissue-specific impaired energy production from food substrates is the unifying feature of disorders classified in group 2. Generalized profound neurologic dysfunction, including severe central hypotonia, coma, and seizures, sometimes with peripheral spasticity or abnormal movements, typifies the clinical presentation. Children with these disorders present with similar clinical phenotypes but are easily separated into four subgroups (A-D) based on associated results of routine

laboratory studies (Table 82.8). Severe refractory generalized motor seizures, often beginning within the first hours after birth, sometimes even prenatally, are the hallmark of subgroup A. Routine laboratory studies (glucose, blood pH, electrolytes, ammonia) are generally normal unless the infant is near extremis and secondary metabolic abnormalities are present. Several inherited disorders are associated with this phenotype; diagnostic differentiation depends on clinical evaluation by an experienced pediatric neurologist or geneticist and the judicious use of specialized diagnostic laboratory tests.

TABLE 82.8

Features of Group 2 Inborn Errors of Metabolism

Clinical Features	Associated Laboratory Findings	Possible Diagnoses	Specialized Diagnostic Testing
Subgroup A			
Profound neurologic dysfunction Severe hypotonia Seizures	No acidosis Normal ammonia Normal glucose	Nonketotic hyperglycinemia Sulfite oxidase or molybdenum cofactor deficiency Pyridoxine- or folinic acid-responsive seizures Peroxisomal disorders Respiratory chain disorders CDG Cholesterol synthesis defects Neurotransmitter synthesis defects	Plasma and CSF amino acid analysis Urine sulfocysteine Urine oxypurines Urine α–aminoadipic semialdehyde Plasma very-long-chain fatty acid analysis Blood and CSF lactate Plasma acylcarnitine Urine organic acids Serum transferrin electrophoresis Plasma sterols CSF neurotransmitters Neonatal onset epilepsy gene sequencing panel
Subgroup B			
Neurologic dysfunction Hypotonia Seizures With severe acidosis ± liver dysfunction ± dilated cardiomyopathy	Severe acidosis Lactic acidosis ± ketosis ± hypoglycemia ± anemia	Congenital lactic acidoses Pyruvate dehydrogenase Pyruvate carboxylase Respiratory chain disorders	Blood and CSF lactate Plasma and CSF amino acid analysis Urine organic acids Diagnostic muscle biopsy to include histology, enzyme analysis
Subgroup C			
Neurologic dysfunction Vomiting Dehydration Hypotonia Coma ± hepatomegaly, liver dysfunction ± dilated cardiomyopathy Triggered by fasting or intercurrent illness	Hypoglycemia No ketones in urine Acidosis ± hyperammonemia ± lactic acidosis	Fatty acid oxidation defects MCAD LCHAD VLCAD CPT II CAT MACD Ketogenesis defects HMG-CoA lyase MCKAT SCOT	Urine organic acids Plasma carnitine Plasma acylcarnitine profile Diagnostic fasting study Fatty acid oxidation studies in cultured skin fibroblasts Gene-specific mutation analysis
Subgroup D			
Neurologic dysfunction triggered by short fast Hepatomegaly	Severe fasting hypoglycemia Lactic acidosis Normal ammonia ± ketosis ± hyperuricemia ± hypophosphatemia	Glycogen storage Glycogenosis 1 Glycogenosis 3 Fructose 1,6-bisphosphatase deficiency	Diagnostic fasting study Enzyme studies in liver Gene-specific mutation analysis

CAT, carnitine acylcarnitine translocase; *CDG,* congenital disorders of glycosylation; *CPT II,* carnitine palmitoyltransferase II; *HMG-CoA lyase,* 3-hydroxy-3-methylglutaryl-CoA lyase; *LCHAD,* long chain 3-hydroxyacyl-CoA dehydrogenase; *MACD,* multiple acyl-CoA dehydrogenase deficiency (also known as glutaric aciduria type 2); *MCAD,* medium chain acyl-CoA dehydrogenase; *MCKAT,* medium chain ketoacyl-CoA thiolase; *SCOT,* succinyl-CoA:oxaloacetate transferase; *VLCAD,* very-long-chain acyl-CoA dehydrogenase.

The amino acid glycine is an abundant neurotransmitter within the central nervous system (CNS). Inherited deficiency of the glycine cleavage system, which removes glycine from its receptor in the neuronal synapse, causes severe unrelenting generalized seizures and profound developmental arrest. The only ubiquitous laboratory finding is an elevated cerebrospinal fluid (CSF/plasma glycine ratio).[10] Sulfite oxidase deficiency, either as a primary genetic defect or secondary to generalized deficiency of its molybdenum-containing cofactor, is another rare but important cause of neonatal-onset seizures. Infantile-onset pyridoxine- or folinic acid-dependent seizure disorders have both been found to be caused by recessively inherited deficiency of α-aminoadipic semialdehyde (α-AASA) dehydrogenase, an intermediate enzyme in the metabolism of the amino acid lysine.[11] Consequently, all neonates with refractory seizures should be screened for these treatable disorders either through measurement of α-AASA in urine or sequencing of the *ALDH7A1* (antiquitin) gene. Profound neurologic dysfunction with seizures is one of many possible clinical presentations of infants with peroxisomal or respiratory chain disorders. Some subtypes of a still expanding list of congenital disorders of glycosylation present with seizures,[12] as do disorders of sterol production such as Smith-Lemli-Opitz syndrome,[13] but these diagnoses are often associated with stereotypic dysmorphic features and anomalies. Finally, disorders of neurotransmitter synthesis should be considered in any infant with idiopathic seizures and neurologic dysfunction, especially if a movement disorder, most commonly dystonia, is also present. Abnormal CSF neurotransmitter levels (5-methyltetrahydrofolate, 5-hydroxyindoleacetic acid, homovanillic acid, 3-methyl-DOPA) are the only associated laboratory diagnostic clue in this latter category of disease.

Severe persistent lactic acidosis is the hallmark of the disorders in subgroup B of early-onset energy deficiency diseases. The presence of metabolic acidosis with an elevated anion gap suggests the possibility of lactic acidosis (subgroup B) or an organic acidemia (see group 3, intoxication types); these are differentiated by measurement of blood lactate and urine organic acid analysis. Blood lactate is most reliably measured on arterial blood or a free-flowing sample drawn from an indwelling central venous catheter. Artifactual elevation of lactate in peripheral venous blood samples is nearly ubiquitous and should be confirmed by lactate measurement in a more appropriate sample. Secondary lactic acidosis resulting from asphyxia, poor tissue perfusion, or tissue necrosis is much more common and may be difficult to differentiate from the congenital lactic acidoses (see also Chapters 76 and 80). Occult cardiac disease, intracranial hemorrhage, or bowel necrosis must considered and ruled out in infants with severe lactic acidosis. Congenital lactic acidosis generally persists despite adequate life support measures, including fluid resuscitation and ventilatory assistance. In certain enzyme deficiencies, the blood lactate level may further increase with IV dextrose infusion. Simultaneous measurements of blood and CSF lactate and amino acids are useful for differentiating primary from secondary lactic acidoses. In congenital lactic acidosis, the CSF lactate level often is higher than the blood lactate level, whereas the CNS is relatively protected from systemic acidosis in secondary lactic acidemias. The blood pyruvate level is elevated in some congenital lactic acidoses such as pyruvate dehydrogenase deficiency. However, accurate measurement of blood pyruvate is difficult and fraught with false-positive elevations. Elevated plasma alanine (which

is measured as part of a plasma amino acid analysis) is a more stable and reliable indicator of pyruvic acidosis, as alanine and pyruvate are in equilibrium. Enzymatic analysis in cultured skin fibroblasts or mitochondria isolated from a fresh muscle biopsy often is necessary to confirm a specific enzyme deficiency.

Children with subgroup C defects present with hypoketotic hypoglycemia, triggered by fasting, metabolic stress, or intercurrent illness. In these disorders, utilization of fatty acids as fuel is impaired. The most common of the fatty acid oxidation defects is MCADD, which occurs in up to 1 : 10,000 Caucasian births. Although fatty acid oxidation and ketogenesis defects may present in the newborn period, particularly in the setting of delayed maternal milk production for exclusively breast-fed infants, the first clinically significant episode may not occur for weeks to months or even years after birth. With extended fasting or intercurrent illness where metabolic demand exceeds available energy supply, severe lethargy acutely develops and then progresses to coma. Recurrent vomiting and consequent dehydration may be associated. Sudden infant death after an overnight fast is an all too frequent initial presentation in up to one-third of infants with fatty acid oxidation defects. Infants who survive may suffer recurrent episodes of fasting or illness-induced coma, leading to progressive CNS damage and permanent disability. Metabolic acidosis (resulting from accumulation of partially oxidized fatty acids or secondary lactic acidosis), hyperammonemia, hepatomegaly and liver dysfunction, and hypertrophic cardiomyopathy may occur during acute metabolic decompensation episodes. Liver histology is typified by severe steatosis. Chronically affected children may exhibit recurrent vomiting, failure to thrive, developmental delay, and muscular hypotonia. Certain disorders that affect oxidation of long-chain fatty acids are frequently associated with recurrent rhabdomyolysis and myoglobinuria (long-chain 3-hydroxyacyl-CoA dehydrogenase [LCHAD] deficiency, trifunctional protein deficiency, very-long-chain acyl-CoA dehydrogenase [VLCAD] deficiency, or carnitine-palmitoyl transferase [CPT]-II deficiency) or pigmentary retinopathy and slowly progressive vision loss (LCHAD or trifunctional protein deficiency). Mothers of infants with fatty acid oxidation disorders (particularly LCHAD or trifunctional protein deficiency) may present with acute liver dysfunction during pregnancy with an affected fetus. This may manifest as acute fatty liver of pregnancy or maternal hemolysis, elevated liver enzymes, or low platelets (HELLP) syndrome. In the affected infant, hypoglycemia (serum glucose <40 mg/dL) with inappropriately low or absent ketone production during a symptomatic episode is the key laboratory finding that leads to suspicion of a disorder in this subgroup. Differentiation of the specific defects requires analysis of urine organic acids and plasma acylcarnitine species. Between episodes, when the child is clinically well, the urine organic acid profile may be completely normal. Acylcarnitine profiles are more consistently abnormal, but both tests, if normal initially, should be repeated on samples obtained during a symptomatic period to absolutely rule out the possibility of a fatty acid oxidation defect. Carnitine is required for normal fatty acid oxidation; long-chain fatty acids are activated to fatty acyl-CoA, then esterified to carnitine by CPT-I on the outer mitochondrial membrane. These acylcarnitine esters are then transported into mitochondria to complete the oxidation process. In fatty acid oxidation defects, the metabolic block leads to accumulation of the fatty acyl-CoA substrate specific to the deficient enzyme; these species appear in blood as acylcarnitine esters. Analysis of plasma

acylcarnitine profiles by tandem mass spectrometry often suggests a specific enzyme deficiency in children with suspected fatty acid oxidation disorders.[14] In the past, diagnostic confirmation may require enzyme analysis in liver tissue or radiometric evaluation of fatty acid oxidation in cultured skin fibroblasts. For the most part, however, these assays have been replaced by sequencing of genes encoding enzymes in the fatty acid oxidation pathway. Two disorders, namely, MCADD[15] and LCHAD deficiency,[16] are associated with relatively common disease-causing mutations. Treatment of all disorders in this subgroup is based on the provision of adequate nonfat calories and prevention of fasting. Generous IV glucose infusion is lifesaving and essential during acute episodes of metabolic decompensation. Chronic dietary therapy is tailored to the specific enzyme deficiency involved. Many practitioners prescribe carnitine supplementation, initially intravenously during an acute episode and later orally, but the efficacy of this intervention has not been formally investigated in any controlled clinical trial, and its use in disorders of long-chain fatty acid oxidation remains controversial.

Hypoglycemia following a short fast of only 4 to 6 hours is highly suggestive of a glycogen storage disease or disorder of gluconeogenesis such as fructose 1,6-bisphosphatase deficiency. These disorders of energy deficiency are classified in subgroup D. These infants appear healthy while fed but quickly become obtunded and hypotonic with fasting hypoglycemia. Hepatomegaly is a prominent physical feature. During acute hypoglycemia, other biochemical derangements, including lactic acidosis, hypophosphatemia, hyperuricemia, and hypertriglyceridemia, are frequently present. Confirmation of the diagnosis may require a provocative fast under controlled conditions with continuous monitoring and, sometimes, measurement of glycogen content or enzymatic analysis on a liver biopsy specimen. Molecular DNA analyses are commonly available for a less invasive approach to diagnostic confirmation in this class of diseases.

Group 3 Inborn Errors of Metabolism

Infants with group 3 IEM display symptoms and a progressive clinical course suggestive of intoxication. In these infants, who appear completely healthy at birth and for the first few days of life, neurologic dysfunction appears as toxic metabolites accumulate with increasing food intake. Initial symptoms may include vomiting and lethargy that progress, perhaps over only a few hours, to complete coma or shock. This specific clinical presentation in particular suggests the possibility of bacterial or viral sepsis; evaluation for infectious disease is entirely appropriate. However, the clinician must remain alert to the possibility of an underlying IEM in a previously healthy infant suffering catastrophic illness within the first days of life. Group 3 IEMs can be subdivided into four subgroups (A-D) based on specific clinical and laboratory findings (Table 82.9).

TABLE 82.9

Features of Group 3 Inborn Errors of Metabolism

Clinical Features	Associated Laboratory Findings	Possible Diagnoses	Specialized Diagnostic Studies
Subgroup A			
Neurologic	Mild acidosis	Maple syrup disease (branched chain ketoacid	Plasma amino acid

deterioration Coma Abnormal movements Hypertonia Sweet odor	Normal lactate ± ketonuria Normal ammonia + urine DNPH test	dehydrogenase deficiency)	analysis Urine organic acid analysis
Subgroup B			
Neurologic deterioration Coma Dehydration	Severe acidosis Severe ketonuria ± hyperammonemia ± lactic acidosis ± hypoglycemia ± neutropenia − urine DNPH test	Organic acidemias Propionic acidemia Methylmalonic acidemia Isovaleric acidemia MCD deficiency Others	Urine organic acid analysis Plasma carnitine levels Plasma acylcarnitine profile Urine acylglycine profile Molecular DNA analysis
Subgroup C			
Neurologic deterioration Coma Seizures Hypotonia ± liver dysfunction	Severe hyperammonemia No acidosis + alkalosis Low BUN Normal glucose Normal lactate	Urea cycle disorders (CPS, OTC, ASS, ASL deficiencies) Triple H syndrome (hyperornithinemia-hyperammonemia-homocitrullinuria)	Plasma amino acid analysis Urine organic acid analysis Urine orotic acid Enzyme studies in liver or fibroblasts Molecular DNA analysis
Subgroup D			
Neurologic deterioration Hepatomegaly Liver dysfunction Cholestatic jaundice	Direct hyperbilirubinemia ± hypoglycemia ± acidosis ± lactic acidosis ± ketosis	Galactosemia Fructosemia Tyrosinemia type 1 Neonatal hemochromatosis Respiratory chain disorders	Urine-reducing substances Plasma amino acid analysis Urine organic acid analysis Urine succinylacetone Enzyme studies Molecular DNA analysis

ASL, Argininosuccinate lyase; *ASS*, argininosuccinate synthetase; *BUN*, blood urea nitrogen; *CPS*, carbamyl phosphate synthetase; *DNPH*, dinitrophenylhydrazine; *MCD*, multiple carboxylase deficiency; *OTC*, ornithine transcarbamoylase.

Maple syrup urine disease ([MSUD] branched-chain ketoacid dehydrogenase [BCKD] deficiency) affects the catabolism of the branched-chain amino acids leucine, isoleucine, and valine and is the only disorder in subgroup A. Affected infants present with coma; abnormal body movements including seizures; and, in contrast to many IEMs, hypertonia and opisthotonus. A severe burst-suppression pattern is the typical EEG abnormality. A sweet body odor, concentrated particularly in urine and cerumen, is often present. Mothers with previously affected children can often diagnose MSUD in a new infant by the presence of this odor. Routine laboratory studies may document mild metabolic acidosis and mild ketosis but normal lactate and ammonia. The branched-chain ketoacids that accumulate in MSUD react only slightly with the urine dipstick test for ketones but readily form a flocculent white precipitate with 2,4-dinitrophenylhydrazine (DNPH) in a urine metabolic screen. The presence and specific identities of branched-chain ketoacids in urine are confirmed by urine organic acid analysis. Plasma amino acid analysis reveals tremendous elevation of leucine with lesser accumulations of valine and isoleucine. The neurologic symptoms associated with MSUD result entirely from leucine intoxication. Valine and isoleucine, which do not cross the blood-brain barrier as readily as leucine, seem to contribute little to the neurologic phenotype. Reduction of leucine levels in the body is the goal of MSUD treatment.[17] Emergency therapy during the initial clinical episode includes dietary protein restriction and IV infusion

of dextrose-containing fluids. Hyponatremia is a common associated feature; IV hydration with hypotonic fluids easily exacerbates this problem. Additionally, leucine accumulates in CSF and brain and is strongly osmotically active. Rapid IV infusion of hypotonic solutions in several instances has led to acute cerebral edema and death. Dextrose solutions containing a minimum of 0.45% saline (one-half normal saline) are essential, but 10% dextrose with normal saline is preferred if the serum sodium is <135 mEq/L. With administration of IV dextrose, mild hyperglycemia secondary to insulin resistance may occur; inclusion of regular insulin (often only 0.05 units/kg body weight/hour) by either IV infusion or subcutaneous injection promotes anabolism, suppresses endogenous protein catabolism, and accelerates leucine clearance. The vitamin thiamine is a cofactor for BCKD; some individuals with BCKD deficiency (usually with a late rather than neonatal presentation) may respond clinically to thiamine supplementation. Oral thiamine (100 mg/day) is often given empirically to determine whether there is any effect on leucine levels. Once the diagnosis of MSUD is confirmed by plasma amino acid analysis, enteral feedings with a medical food that is free of branched-chain amino acids should be initiated even if the infant is comatose and nasogastric feedings are necessary. Parenteral hydration should continue until results of urine ketone and DNPH tests are negative and full enteral feeds are reestablished. On this regimen, plasma valine and isoleucine levels plummet rapidly, but several days may be required before plasma leucine normalizes. Valine and isoleucine deficiencies that frequently develop on this regimen stimulate endogenous protein catabolism, which impairs reduction of blood leucine, prolongs neurologic impairment, and chronically may be associated with symptoms of protein insufficiency (hair loss, skin breakdown, growth failure). Therefore valine and isoleucine supplementation (50–100 mg/kg/day) is required. Chronic lifelong therapy involves dietary protein restriction and provision of sufficient energy and amino acids in a leucine-free synthetic medical food. Despite this effort, infants who suffered prolonged severe leucinosis as neonates often exhibit significant developmental disability. Early diagnosis and appropriate therapy critically enhance neurodevelopmental outcome.

Severe ketoacidosis is the hallmark of IEMs in subgroup B, the organic acidemias. Methylmalonic, propionic, and isovaleric acidemias are the most common disorders in this subgroup. Infants with organic acidemia present with catastrophic episodes of vomiting, dehydration, and coma. Hypoglycemia, lactic acidosis, hyperammonemia, neutropenia, or pancytopenia may be associated findings depending on the specific IEM. The urine dipstick test for ketones is strongly positive, but in contrast to MSUD, little precipitate forms following the addition of DNPH reagent to the urine. Identification of the specific offending organic acid is accomplished by urine organic acid analysis using gas chromatography–mass spectrometry. Diagnostic confirmation may require enzymatic analysis in tissues such as leukocytes, liver, or cultured skin fibroblasts. Molecular DNA analysis is increasingly available as a diagnostic modality as well. Cessation of protein intake, vigorous rehydration with dextrose-containing fluid, and management of acidosis with sodium bicarbonate infusion are the mainstays of emergency management. In severely acidotic patients, especially with associated hyperammonemia, hemodialysis may be useful for quickly removing both ammonia and the offending organic acid with the goal of minimizing CNS damage. IV infusion of l-carnitine (100–300 mg/kg/day) assists with the removal of the offending organic acid and

prevents secondary carnitine deficiency. Oral l-glycine supplementation has a similar role in certain IEMs, most notably isovaleric acidemia. Chronic therapy is tailored to the specific enzyme deficiency but often involves dietary protein restriction and provision of a synthetic medical food supplying sufficient energy and amino acids. Recurrent episodes of life-threatening ketoacidosis and coma, generally triggered by fasting or intercurrent illness, are often the greatest long-term clinical difficulties.

Advancing dietary protein intake and normal protein catabolism during the first few days of life lead to severe hyperammonemia in infants with urea cycle and allied disorders (subgroup C). The clinical presentation is nonspecific, with progressive vomiting and neurologic dysfunction. Routine laboratory studies are generally deceptively normal, although the BUN often is below the limits of detection in infants who are unable to synthesize urea. No acidosis is present unless the infant is apneic or hypoperfused and secondary lactic acidosis has developed. Most severely hyperammonemic infants demonstrate respiratory alkalosis secondary to Kussmaul-like hyperventilation triggered by cerebral edema. Detection of hyperammonemia is the critical diagnostic key. The blood ammonia level must be measured in any child with acute-onset obtundation without a clear etiology such as trauma. Determination of the specific IEM involved requires analysis of blood amino acids and urine organic acids. Diagnostic confirmation is now often accomplished through molecular DNA analysis of specific genes involved in the urea cycle, but in rare instances, enzyme analysis in liver or for a few defects in cultured skin fibroblasts may yet be necessary if molecular testing is inconclusive. Provision of nonprotein energy and suppression of protein catabolism through IV dextrose infusion are essential, as in the organic acidemias, but emergency hemodialysis to rapidly decrease blood ammonia is absolutely required if any possibility of favorable neurodevelopmental outcome is to be preserved. Ammonia clearance by exchange transfusion or peritoneal dialysis is insufficient to accomplish this goal. Even with prompt hemodialysis, the metabolic derangement in some infants is so severe that little sustained decrease in blood ammonia is observed. Despite aggressive therapy, neonatal-onset urea cycle disorders are frequently lethal. The few infants exposed to hyperammonemia for a prolonged period who, because of extraordinary life support efforts, survive are often profoundly neurologically impaired. On the other hand, clinical outcome is favorable in cases where blood ammonia levels rapidly correct on hemodialysis. This dichotomy in outcome presents a considerable dilemma to the intensivist faced with these critical treatment decisions. In practice, hemodialysis should be attempted as soon as possible after the discovery of hyperammonemia unless clinical signs of severe permanent CNS damage are already present. Disorder-specific therapy should continue for infants whose blood ammonia levels immediately normalize with hemodialysis. Aggressive life support measures should be limited for infants with recalcitrant hyperammonemia. Following dialysis, generous IV hydration and provision of nonprotein calories should continue. The amino acid arginine, normally synthesized through the urea cycle, becomes an essential amino acid that must be provided exogenously in urea cycle disorders. l-Arginine hydrochloride is available for IV administration as 10% solution and should be added to the IV fluid bag to give 0.66 g arginine HCl/m^2/day (6 mL/kg/day in infants). The ammonia scavenging agents sodium phenylacetate and sodium benzoate are available as a combined IV solution. Administration of this solution

dramatically improves ammonia clearance and is indicated for the acute management of the proximal urea cycle disorders, but it is associated with severe adverse effects including metabolic acidosis and erosive gastritis if administered inappropriately. This solution should be used only in consultation with a provider experienced with its administration and with careful monitoring. Long-term therapy is based on dietary protein restriction and oral l-arginine or l-citrulline supplementation. Oral administration of sodium benzoate, sodium phenylbutyrate, or glycerol triphenylbutyrate as ammonia scavengers is often prescribed. Episodes of fasting or illness-induced hyperammonemic coma frequently recur. Management of recurrent hyperammonemia in a patient known to have a urea cycle disorder is similar to that outlined earlier but can be tailored to the specific defect. Liver transplantation is a viable treatment option for individuals suffering recurrent hyperammonemia and chronic clinical and developmental difficulties despite adequate nutritional and medical therapy.

Hepatomegaly, liver dysfunction, and cholestatic jaundice in association with neurologic deterioration are the central presenting features of IEM in subgroup D. For all of these disorders, the accumulating toxin is particularly damaging to hepatocellular function. Hypoglycemia, acidosis, and mild ketosis may be present. Bacterial infection, particularly urinary tract infection, bacteremia, or meningitis, often caused by *E. coli* or other gram-negative enteral flora, is a frequent occurrence in infants with galactosemia. The specific diagnosis is suggested by the clinical scenario and by the results of screening laboratory studies. Infants with this clinical presentation who are breast-fed or receiving cow's milk–based infant formula are at risk for symptoms of galactosemia, given that lactose (milk sugar) is a disaccharide of galactose and glucose. Infants receiving exclusively soy milk–based formula ingest little galactose. The predominant dietary carbohydrates in soy formula are fructose and glucose, so infants fed soy formula who have this clinical presentation are likely to have fructosemia rather than galactosemia. More typically, infants with fructosemia present clinically after the introduction of fruit to their diet. In either galactosemia or fructosemia, reducing sugars are detected in urine following ingestion of the offending sugar by the urine-reducing substance test (Clinitest). Plasma tyrosine level is elevated, urine organic acid analysis displays metabolites from the tyrosine pathway, and succinylacetone is detected in the urine of children with tyrosinemia type I (fumarylacetoacetate hydrolase deficiency). Neonatal hemochromatosis can be diagnosed only on liver biopsy by staining for iron. Diagnostic confirmation differs for each disorder but may include further metabolite analyses, enzymatic analysis in tissue, or molecular DNA testing. Initial therapy is nonspecific: cessation of enteral feeding and IV infusion of dextrose-containing fluid. Once the exact diagnosis is known, a specific therapy plan can be developed. For the carbohydrate disorders, the offending sugar must be reduced or eliminated from the diet. Galactosemic infants are fed soy milk–based formulas only. After weaning, ingestion of dairy products, including baked goods prepared with dairy products, is strictly avoided. Similarly, fructosemic individuals must strenuously avoid any fructose-containing foods. In prior eras, cirrhosis and liver failure were the inevitable outcome in children with tyrosinemia type I unless they received a liver transplant. Effective therapy that prevents liver degeneration in tyrosinemia has now been developed. The oral drug 2-(2-nitro-4-trifluoro-methylbenzoyl)-1,3-cyclohexanedione (NTBC) blocks tyrosine metabolism upstream from FAH and

prevents accumulation of the intermediate metabolites that are toxic to hepatocytes.[18] This medication was highly successful in preventing cirrhosis in two separate clinical trials and has been approved by the US Food and Drug Administration for general use. The long-term efficacy of NTBC therapy, particularly with regard to the incidence of hepatic adenoma, a common complication of tyrosinemia I, has yet to be proved.[19]

Summary

Most IEMs with symptom onset in the neonatal period emerge as one of the clinical presentations described. As mentioned previously, many of these IEMs have milder or late-onset forms that present with identical symptoms as described, but months or years after birth and often following the stress of fasting or intercurrent illness. These clinical scenarios provide a framework for the recognition, initial evaluation, and emergency treatment of infants with IEM. The remainder of this chapter focuses on the differential diagnosis of select clinical situations encountered in the pediatric intensive care unit.

Metabolic Acidosis

The key to the differential diagnosis of metabolic acidosis is calculating the serum anion gap ($Na - [Cl^- + HCO_3]$. This calculation, normally 10 to 15 mM, represents the unmeasured negative ions, predominantly albumin, in blood. Normal anion gap acidosis (low serum HCO_3 but normal anion gap) is caused by excess bicarbonate loss from either the gut (diarrhea) or kidney (renal tubular acidosis). An elevated or so-called positive anion gap suggests the presence of another unmeasured anion. Incidentally, a low serum anion gap may be seen in extreme hypoalbuminemia, as occurs in nephrotic syndrome (see Chapters 75 and 76).

The differential diagnosis of positive anion gap metabolic acidosis in children is similar to that of adults (eg, a favorite mnemonic may be applied, such as MUDPILES or KETONES), but with the addition of another class of acidoses, the IEMs. Poisoning with methanol, ethanol, paraldehyde, isoniazid, or salicylates can be readily ruled out by history or drug screen. Uremia is also easily discovered by laboratory evaluation. The most common etiologies of a positive anion gap acidosis in children are ketosis, lactic acidosis, or a combination of the two. Extreme dehydration can cause both ketosis and lactic acidosis; these abnormalities are readily corrected with vigorous parenteral rehydration with dextrose-containing fluids. Persistent lactic acidosis suggests ongoing tissue damage from hypoxemia, hypoperfusion, or, more rarely, an inborn error of mitochondrial metabolism. It should be remembered that several organic acids, such as propionic and methylmalonic acids, react with the urinary ketones dipstick. These pathologic organic acids can be differentiated only from the more typical ketones, 3-hydroxybutyric and acetoacetic acids, by urine organic acid analysis. Severe positive anion gap metabolic acidosis that cannot be easily explained by the clinical context, especially if it occurs recurrently or is recalcitrant to parenteral fluid therapy, suggests an inborn error of organic acid metabolism and should be evaluated with a battery of screening metabolic studies including plasma amino acid analysis, urine

organic acid analysis, and urine qualitative metabolic screen.

Hypoglycemia

Hypoglycemia can be defined as a blood glucose concentration less than 40 mg/dL.[20] Low blood glucose may be present within the first few hours after birth, especially in preterm or low-birth-weight infants, but the capacity for effective gluconeogenesis and fatty acid oxidation is induced within the first day after birth. Therefore blood glucose less than 40 mg/dL is distinctly unusual after the first 24 hours of life, particularly in infants who have started feeding, and should be thoroughly investigated (Fig. 82.2). A review of hypoglycemia in infants and children along with a useful diagnostic algorithm has been published.[21] A detailed medical history and careful physical examination are essential to discovering the cause of hypoglycemia. The timing of hypoglycemia relative to feeding is a critical item of historical information. Persistent or postprandial hypoglycemia suggests hyperinsulinism. Hypoglycemia after a short fast (3–6 hours) along with permanent hepatomegaly suggests a glycogen storage disorder. Hypoglycemia following a longer fast (8–12 hours) suggests a defect in gluconeogenesis or a problem with utilization of fatty acids. The presence of ketones in urine (as measured qualitatively by urine dipstick) or in serum (quantitative measurement of 3-hydroxybutyrate or acetoacetate) is an important clue to the etiology of hypoglycemia. Ketosis during hypoglycemia demonstrates that insulin secretion is appropriately suppressed and that fatty acid mobilization and oxidation are intact. Glycogen storage disorders, gluconeogenic defects, and defects of ketone utilization all are associated with ketosis. The absence of ketogenesis during hypoglycemia suggests that either insulin levels are inappropriately elevated or fatty acid oxidation is blocked. An important caveat to this rule is that infants younger than approximately 1 week cannot normally produce enough ketones during fasting to trigger a positive urine dipstick test for ketones. The absence of urine ketones in an infant younger than 1 week does not contribute to the differential diagnosis of hypoglycemia. On the other hand, serum ketones increase with fasting even in neonates, and this test provides a valuable result in the investigation of hypoglycemia. In hypoketotic hypoglycemia, measurement of total serum free fatty acids provides further useful diagnostic information. During fasting, insulin secretion normally is suppressed, free fatty acids are mobilized into circulation from peripheral adipose tissues, and ketones are produced by oxidation of fatty acids in liver. A low serum total free fatty acid level during hypoketotic hypoglycemia strongly suggests inappropriate insulin secretion, even if insulin levels do not appear to be dramatically elevated. Hypoketotic hypoglycemia in association with elevated serum total free fatty acids suggests a defect in fatty acid oxidation.

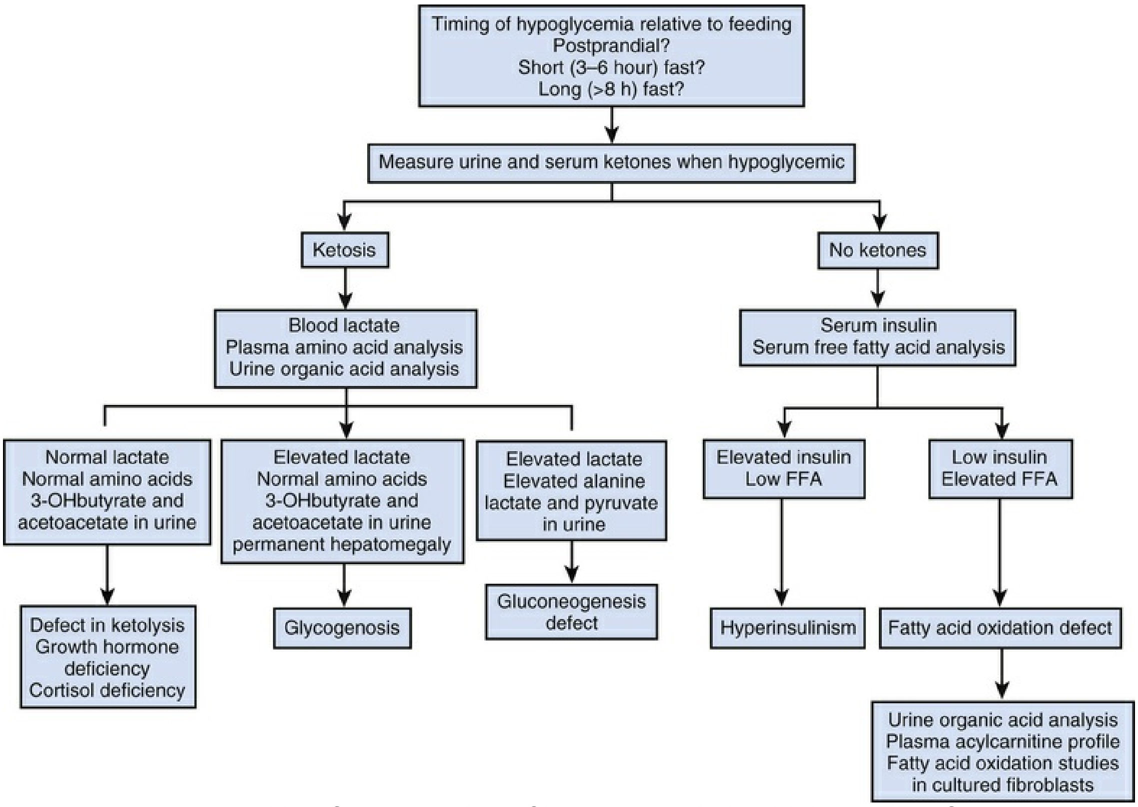

FIG. 82.2 Algorithm for evaluation of hypoglycemia in children. *FFA*, free fatty acid; *SCOT*, succinyl-CoA oxoacid transferase.

The importance of treating hypoglycemia cannot be overemphasized as affected individuals are at high risk for seizures and permanent brain damage.[22] After appropriate diagnostic studies are obtained, hypoglycemia should be treated with IV glucose administration at the rate of normal hepatic glucose production, approximately 10 mg glucose/kg body weight per minute or 150 mL/kg per day of a 10% solution until the underlying disorder is identified and more appropriate therapies can be initiated.

Hypoketotic hypoglycemia with low serum total free fatty acids suggests hyperinsulinism. Hyperinsulinism presenting in the newborn period may be caused by intrauterine exposure to elevated glucose levels (maternal diabetes mellitus), familial hyperinsulinemic hypoglycemia (defect in the sulfonylurea receptor), or hyperammonemia/hyperinsulinism syndrome (abnormality in regulation of insulin secretion secondary to mutation in glutamate dehydrogenase). Infants with hyperinsulinism often are obese and require glucose infusions greater than 10 mg/kg/min to maintain normoglycemia. Glucagon administration (0.03 mg/kg, up to 1-mg total dose) reverses hypoglycemia in hyperinsulinism. Oral diazoxide has not been shown to be efficacious in most neonatal cases; however, it can be effective in normalizing blood glucose levels in patients who have infantile forms of hyperinsulinism, including hyperammonemia/hyperinsulinism syndrome.[23] This usually is given at doses of 5 to 10 mg/kg/day divided into three doses. When initially administered, it is given along with glucose and glucagon. Efficacy of diazoxide is defined by demonstrating normal preprandial and postprandial glucose concentrations after overnight fasting and after having stopped IV glucose and any other medications for 5 consecutive days.

Hypoketotic hypoglycemia with elevated serum total free fatty acids, usually occurring following an extended fast (8–12 hours) or in association with an intercurrent illness, suggests a defect in fatty acid oxidation. The clinical presentation of fatty acid oxidation disorders has been described. Although inherited deficiency of at least nine different enzymatic steps in the mitochondrial β-oxidation pathway has been described, the clinical presentation of infants and children with these diseases is stereotypically similar and can be differentiated only by appropriate metabolic testing. In all cases, vigorous hydration with dextrose-containing parenteral fluids is lifesaving. Fasting avoidance is key to the long-term treatment and prevention of hypoglycemic episodes.

Infants and children with glycogen storage disorders present with hypoglycemia and permanent hepatomegaly. Hypoglycemia in these disorders is poorly responsive to glucagon administration. Enzymatic defects affecting glycogen synthesis, including glycogen synthase deficiency (GSD-0), as well as defects in glycogen breakdown, such as debranching enzyme deficiency (GSD-III), result in hypoglycemia. Glycogen synthase deficiency usually presents as severe morning hypoglycemia with hyperketonemia and low lactic acid and alanine. Debranching enzyme deficiency results in hypoglycemia secondary to limitation of glucose release from the outer branches of the glycogen molecule. Ketosis is present in GSD-III as the body attempts to generate fuel by increased fatty acid oxidation. Furthermore, the gluconeogenesis pathway is intact; thus hypoglycemia is much milder. In glucose 6-phosphatase deficiency (GSD-1a) and glucose 6-phosphate translocase deficiency (GSD-1b), hypoglycemia usually is apparent 2.5 to 3 hours postprandial as these disorders not only affect glucose release from glycogen but also disrupt gluconeogenesis. Individuals with these disorders have lactic acidosis, ketosis, and hyperuricemia in addition to hepatomegaly.

Hypoglycemia following a longer fast (8–12 hours) suggests a defect in gluconeogenesis, ketogenesis, ketolysis, or fatty acid oxidation. Fructose 1,6-bisphosphatase, a disorder of gluconeogenesis, presents as fasting hypoglycemia but also with metabolic decompensation following fructose ingestion. Ketonemia and lactic acidemia are major features, in addition to the hypoglycemia. The ketone synthesis defects that present with fasting hypoketotic hypoglycemia include 3-hydroxy-3-methylglutaryl-CoA synthase deficiency and 3-hydroxy-3-methylglutaryl-CoA lyase deficiency. These patients have hypoglycemia in combination with normal blood lactate but no ketonuria. Infants with 3-hydroxy-3-methylglutaryl-CoA lyase deficiency also are hyperammonemic. Defects in succinyl-CoA oxoacid transferase and methylacetoacetyl-CoA thiolase represent ketolysis defects. Although the consistent biochemical abnormality is severe ketoacidosis, hypoglycemia also can be seen. Blood lactic acid and ammonia concentrations usually are normal.

Cardiomyopathy and Inborn Errors of Metabolism

Cardiomyopathies, as a rule, are rare. Studies undertaken by the Pediatric Cardiomyopathy Registry have determined that the overall annual incidence is 11.8 per million patient-years and that the incidence was higher in children younger than

1 year than in those between 1 and 18 years old.[24] In this regional study, 40% of cases were hypertrophic cardiomyopathies, 49% of cases were dilated cardiomyopathies, 3% of cases were restrictive or other types, and 8% were unspecified. Further study revealed that of cases of hypertrophic cardiomyopathy, 16% had an identifiable IEM as the underlying cause. These causes included disorders of glycogen metabolism (5%), mucopolysaccharide metabolism (4%), oxidative phosphorylation (5%), and fatty acid metabolism (2%). In the cases of dilated cardiomyopathy, 5% were found to be of a metabolic etiology with disorders of glycogen metabolism (1%), mucopolysaccharide metabolism (2%), and oxidative phosphorylation (2%) as the recognizable underlying cause. Thus it is important to consider IEM in the differential diagnosis of any child with dilated or hypertrophic cardiomyopathy. Because the prevalence of underlying metabolic disorders is so high, some authors have recommended that all children with cardiomyopathy undergo metabolic screening, including blood lactate, plasma amino acid analysis, urine organic acid analysis, urine metabolic screening (particularly for the detection of excessive urinary mucopolysaccharides), plasma carnitine levels, and plasma acylcarnitine profile (Box 82.3).[25] Additionally, serum creatine kinase (CK) should be measured to exclude muscular dystrophy.

Box 82.3

Screening Laboratory Studies for Evaluation of Cardiomyopathy

- Blood lactate
- Serum creatine kinase
- Plasma amino acid analysis
- Urine organic acid analysis
- Urine mucopolysaccharide screen
- Plasma carnitine levels
- Plasma acylcarnitine profile

Autosomal dominant hypertrophic cardiomyopathy has an incidence of 1 : 500 but demonstrates extremely variable penetrance. Mutation in genes encoding structural sarcomeric proteins is a frequent cause of dominant hypertrophic cardiomyopathy. More than 140 mutations in 15 different genes have been identified.[26]

Cardiomyopathy may be a complicating feature of several IEMs (Table 82.10), but with a few exceptions, other associated symptoms or physical examination findings at the time of presentation point toward the appropriate diagnosis. Broadly, the pathogenesis of cardiomyopathy in IEMs is either myocardial energy deficiency, as occurs in the dilated cardiomyopathy associated with several organic acidemias, or excessive storage of complex molecules in the heart, as occurs in the hypertrophic cardiomyopathy of mucopolysaccharidoses such as Hurler syndrome.

Cardiomyopathy occurs as the sole initial clinical manifestation in a relatively restricted list of metabolic diseases, including autosomal recessively inherited deficiency of the cellular carnitine transporter, fatty acid oxidation disorders, glycogenosis types II and IX, and disorders of oxidative phosphorylation. The carnitine transporter defect is caused by deficiency of the sodium-dependent transporter OCTN2, which is responsible for transporting carnitine from the circulation into tissues including cardiac and skeletal muscle.[27] Dilated cardiomyopathy with symptoms of heart failure generally presents within the first years of life and is associated with severely low plasma total carnitine levels. Cardiac function improves dramatically after carnitine supplementation, and cardiomyopathy rarely recurs if carnitine is continued.

TABLE 82.10

Cardiomyopathy and Inborn Errors of Metabolism

Cardiomyopathy as the sole or key presenting feature	Carnitine transport defect
	Fatty acid oxidation defects including: VLCAD deficiency Mitochondrial trifunctional protein deficiency Carnitine palmitoyltransferase deficiency
	Glycogen storage disease type II (Pompe)
	Glycogen storage disease type IX (phosphorylase B kinase deficiency)
	Disorders of oxidative phosphorylation (Mitochondrial myopathy)
Cardiomyopathy as a secondary feature	Organic acidemias including: Propionic acidemia Methylmalonic acidemia 3-methylglutaconic aciduria D-2-hydroxyglutaric aciduria Biotinidase deficiency
	Glycogen storage disease type III
	Glycogen storage disease type IV
	Mucopolysaccharidoses
	Congenital disorders of glycosylation
	Congenital myotonic dystrophy
	Congenital muscular dystrophies

VLCAD, very-long-chain acyl-CoA dehydrogenase.

Hypertrophic cardiomyopathy resulting from myocardial steatosis may be an isolated presenting feature in several disorders of fatty acid oxidation, particularly those affecting long-chain fatty acid metabolism such as VLCAD or mitochondrial trifunctional protein deficiencies. Saudubray and colleagues[28] examined a series of 109 patients with fatty acid oxidation defects and found that cardiac involvement, including hypertrophic cardiomyopathy or arrhythmia, was apparent at presentation in 51% of cases. Fatty acid oxidation disorders are most reliably detected by analysis of plasma acylcarnitine profiles by tandem mass spectrometry. Long-chain fatty acids are activated to CoA derivatives and then esterified to carnitine prior to transport into mitochondria for β-oxidation. In fatty acid oxidation disorders, especially during acute metabolic decompensation, acylcarnitine species accumulate in plasma and provide a diagnostic profile that is specific to a given enzyme deficiency. Confirmation of the diagnosis may require enzymatic analysis in cultured fibroblasts or mutation analysis. Once the diagnosis of a long-chain fatty acid oxidation disorder has been established, restriction of dietary long-chain fat intake and provision of medium-chain triglyceride oil as an alternative fuel source for the myocardium often reverses cardiomyopathy. Cardiac support measures,

including extracorporeal membrane oxygenation, may be necessary for as long as 1 to 2 weeks after presentation before heart function improves.

Glycogen storage disease type II (acid α-glucosidase deficiency; Pompe disease) is a disorder of lysosomal glycogen accumulation that frequently presents as hypertrophic cardiomyopathy, yielding the classic boot-shaped radiographic appearance of the cardiac silhouette. Skeletal myopathy manifesting as severe hypotonia may complicate the presentation. Confirmation of the diagnosis requires measurement of enzyme activity in skeletal or cardiac muscle or cultured fibroblasts. In the past, treatment has only been supportive, but enzyme replacement therapy is now available. Intravenous infusion of recombinant acid α-glucosidase every other week has led to improved cardiac function, neuromuscular development, and survival in infants with Pompe disease.[29] However, antibody formation against the drug in some infants with subsequently decreased treatment effectiveness remains a clinical problem.

Myocardial function is highly dependent on mitochondrial oxidative phosphorylation; up to 30% of the total myocardial volume is composed of mitochondria.[30] Dilated or hypertrophic cardiomyopathy is a frequent presenting feature in infants with severe defects of mitochondrial oxidative phosphorylation. Skeletal muscle myopathy, liver dysfunction, renal tubulopathy, bone marrow failure, or CNS abnormalities may occur. Chronic lactic acidosis, if present, is an important indicator of mitochondrial dysfunction. Screening metabolic laboratory studies demonstrate nonspecific abnormalities associated with chronic lactic acidosis. Definitive diagnosis requires histologic evaluation of skeletal muscle and measurement of respiratory chain enzyme activities. Isolated deficiency of cytochrome c oxidase (COX or complex IV) and reduced nicotinamide adenine dinucleotide (NADH)-ubiquinone oxidoreductase (complex I) of the mitochondrial respiratory chain are the most common oxidative phosphorylation defects presenting with cardiomyopathy. Although some protein subunits of complexes I and IV are encoded by mtDNA, most infant-onset isolated complex deficiencies probably are the result of autosomal-recessively inherited deficiency of nuclear-encoded respiratory chain subunits or of chaperone proteins that ensure proper assembly of functional complexes. For instance, hypertrophic cardiomyopathy caused by functional COX deficiency has been associated with mutations in nuclear COX subunit genes[31,32] or nuclear genes for COX-associated proteins SCO1 and SCO2.[33]

Cardiomyopathy may be seen in several other IEMs, but in these disorders, other physical or biochemical features are generally apparent at initial clinical presentation. For instance, dilated cardiomyopathy may complicate propionic acidemia during acute metabolic decompensation, but features of severe metabolic acidosis, vomiting, dehydration, coma, and possibly hyperammonemia are part of the initial clinical presentation.

Metabolic Myopathies and Rhabdomyolysis

Rhabdomyolysis is a clinical syndrome resulting from skeletal muscle injury and release of potentially toxic substances into the circulatory system. Acute onset of severe muscle pain associated with increased serum CK levels is the hallmark of the disorder. In extreme cases, massive myoglobinuria may cause acute renal

insufficiency. Although trauma and direct muscle injury are by far the most common causes of rhabdomyolysis, inborn errors of muscle metabolism should be considered in the differential diagnosis of rhabdomyolysis occurring at any age. In the absence of a history of trauma, the differential diagnosis of acute rhabdomyolysis should include drug or toxin exposure, muscle hypoxia (often associated with seizures), temperature alterations, inflammatory diseases, and IEMs. Because muscle contraction depends on adenosine triphosphate (ATP) generated by the mitochondrial electron transport chain, it follows that any process that impairs muscle ATP synthesis or that results in energy expenditure that surpasses ATP production could lead to rhabdomyolysis. The clinical history should lead toward the appropriate diagnosis. A family history that includes rhabdomyolysis or a history in which more than one episode of exercise-induced rhabdomyolysis has been observed should induce suspicion of a metabolic disorder. Along with muscular dystrophy and endocrine etiologies (hypothyroidism, hyperthyroidism, diabetic ketoacidosis, pheochromocytoma), glycolytic defects, fatty acid oxidation disorders, purine biosynthetic disorders, and disorders of mitochondrial oxidative phosphorylation should be considered if historical elements do not direct toward the more common etiologies. As described previously, the fatty acid oxidation disorders can be detected by urine organic acid analysis and plasma acylcarnitine profile. Chronic lactic acidosis may be a clue to a disorder of oxidative phosphorylation. Measurement of blood lactate level before and after an exercise treadmill protocol may help detect a respiratory chain defect if the postexercise lactate level is severely elevated. Definitive diagnosis of a mitochondrial disorder requires histologic and enzymatic analysis of a fresh muscle biopsy. The glycolytic defects of phosphofructokinase and phosphoglycerate mutase deficiencies along with myophosphorylase deficiency (glycogen storage disease type V or McArdle disease) cause severe recurrent rhabdomyolysis; their detection requires enzymatic analysis of muscle tissue. Likewise, myoadenylate deaminase deficiency, a defect in purine catabolism, and CPT-II deficiency are also diagnosed by measurement of the enzyme activities in muscle.

Neonatal Screening

Newborn screening for IEMs was first introduced in the 1960s, with screening for phenylketonuria. Technologic advances, most significantly the introduction of tandem mass spectrometry for mass screening, have greatly increased the number of disorders that can be identified by analysis of a dried blood spot on a filter paper card.[34] An expert review conducted by the American College of Medical Genetics led to the recommendation that 29 core conditions, including several aminoacidopathies, fatty acid oxidation defects, and organic acidurias detectable by tandem mass spectrometry, should be included in the panel of disorders screened.[29] As of 2009, all states in the United States and most of Europe have now adopted this recommendation. The cost versus benefits of expanded screening, whether to include specific rare or poorly treatable disorders in the screening panel, and the availability of adequate follow-up resources continue to be debated, but a general consensus has emerged that expanded newborn screening is an effective tool for identifying IEM early in life, allowing for the initiation of therapy, often before the infant becomes symptomatic, and for preventing morbidity and mortality associated

with IEM.[35] It must be remembered, however, that newborn screening is just that—a screen—and both false-positive and false-negative results are possible. Thus the astute clinician must remain cognizant of the fact that in an ill infant, a normal newborn screen is reassuring but should not be taken as absolute proof-positive that an IEM identifiable on newborn screening is not present. Appropriate screening laboratory evaluation and emergency treatment should be instituted if clinical signs and symptoms of an IEM are present in a sick child.

Conclusion

Inborn errors of metabolism are individually rare but collectively will make not-infrequent appearances in a busy pediatric intensive care unit. The signs and symptoms of IEM may be nonspecific and often overlap extensively with more common disorders. When clinical suspicion of an IEM arises, screening biochemical genetic laboratory studies must be ordered. Further confirmatory testing often is necessary if screening laboratory tests point toward a specific disease. Confirmatory testing and disease-specific therapy should be instituted following consultation with a biochemical genetics specialist. If detected and treated early, the clinical outcome for many IEMs can be favorable.

CHAPTER 83

Genetic Variation in Health and Disease

David Jardine

PEARLS

- The DNA from two unrelated humans differs by approximately 0.1%.
- Genetic variation occurs on many different scales, with the smallest being single nucleotide polymorphisms (SNPs) and the largest being chromosomal nondisjunction.
- Mutations originating in somatic cells are not inherited; only those mutations occurring in germline cells are inherited.
- Mutations occurring in somatic cell lines are responsible for a number of disorders, including many nonhereditary cancers.
- Monogenic traits tend to follow Mendelian patterns of inheritance. A relatively small proportion of the inherited burden of disease is attributed monogenic traits. A much larger portion of the inherited burden of disease is caused by complex traits in which many genes contribute to a disease phenotype.
- Genome-wide association studies (GWASs) have great potential to reveal genetic variants that are associated with disease phenotypes; however, GWAS may be difficult and expensive to conduct because a large number of patients may be required to achieve adequate study power.
- Population stratification refers to systematic differences in allele frequencies among subpopulations with different ancestries. This must be carefully considered before determining the applicability of the results of a genetic study to a new population.

Introduction

After the discovery of the structure of DNA in 1953,[1] progress in understanding the genetic basis of human disease was painfully slow. Almost 40 years later, in 1989, the sequence for the cystic fibrosis gene was published, making it one of the first disease-associated genes to be fully sequenced. Automated sequencing of DNA made this process faster and cheaper, but managing the flood of data provided new

challenges. The incorporation of computer technology addressed these problems by performing the tedious work of sequence alignment and managing the ever-increasing volume of sequence data. In the last decade of the 20th century, the continued improvement of these two innovations made feasible the Human Genome Project. By 2003, five years after this broad international collaboration was fully under way, sequencing of the first complete version of the human genome was publicly available.[2,3] Subsequent work has been directed at refining the information contained in the reference human genome and in understanding genetic variation in the population. Continued improvements in sequencing technologies have made this endeavor faster, cheaper, and more accurate. The public cost of sequencing the first human genome was estimated to have been approximately $3 billion (the Human Genome Project). The current cost of sequencing a human genome is now $1,000 and is declining rapidly. As information about human genetic variability becomes more readily available, it will have major implications for science and medicine. In an example that is particularly relevant to pediatric critical care, the understanding of the genetic basis of sepsis is rapidly expanding.[4] Translating these findings to relevant clinical interventions will require time; however, it is certain that knowledge of a patient's genetic makeup will be an important therapeutic consideration within the next few years. Although the era of genetic medicine may seem far off, the feasibility of using rapid whole genome sequencing for the diagnosis of monogenic diseases in an ICU has already been demonstrated.[5] Understanding the potential and limitations of high-throughput genetic screening will have increasing relevance to the practice of medicine, especially in the critical care setting where the illnesses are life threatening and risks of complications and toxicity are great.

Sequence Variation in Health and Disease

The human genome consists of approximately 3 billion DNA base pairs partitioned into 23 chromosome pairs. In spite of the seemingly great differences between individual human beings (phenotype), the genetic differences between individuals is approximately 0.1%.[6] Nevertheless, human genetic variability accounts for a large portion of the differences in susceptibility to disease, rates of aging, and longevity. To understand human genetic variability, genomes from people of varying ethnic origins have been sequenced. These genomes serve as references to understand genetic variations between and within different human subpopulations.

Scale of Mutational Event

Variation can occur on several different scales (Table 83.1). With a few exceptions, before the widespread availability of sequencing technology, the only chromosomal changes that could be documented were those that were observable through a light microscope. These variants can include chromosomal aneuploidies, rearrangements, heteromorphisms, and fragile sites[7] and are referred to as a cell's karyotype. In general, these structural variants must encompass sections of DNA greater than 3 million base pairs in size in order to be visible microscopically. Compared with DNA variants detectable by sequence analysis, the microscopically detectable structural

variants are relatively uncommon.

TABLE 83.1

Variation	Size	Change Compared With Reference Genome
SNP (single nucleotide polymorphism)	1 base pair	A single base pair is altered
Indel (insertion or deletion)	1-1000 base pairs	A small region of DNA is inserted or deleted
CNV (copy number variation)	1000-3 million base pairs	The number of copies of a section of DNA is increased or decreased

After the first two reference versions of the human genome were published in 2001, an intensive effort was launched to detect variation at the single nucleotide polymorphism (SNP) level. Soon afterward, improved analytic techniques enabled efficient detection of submicroscopic structural variants (1–3 million base pairs). It now appears that submicroscopic structural variants contribute at least as much variability to the human genome as SNPs.[7,8]

SNP: A single nucleotide polymorphism (SNP) is the smallest change that can occur within a DNA sequence. This change occurs when one nucleotide is substituted for another in the DNA sequence. By convention, a change in a single nucleotide is referred to as an SNP if the change is found in ≥1% of the subpopulation to which the individual belongs. If the altered nucleotide is found in <1% of the reference subpopulation, it is referred to as a *mutation.* The frequency of occurrence of variation at the single nucleotide level (SNP vs. mutation) does not correlate with the risk of an altered phenotype. Both common and rare variants can have profound effects on the phenotype or can be silent.

Nucleotide level variation is heterogenous in different human subpopulations. In other words, the SNPs in people of African, Asian, and European origin differ markedly from one group to another. For this reason, it is important to consider the population structure when interpreting studies on genetic variation.

Indel: When one or more nucleotides are ***in***serted or ***del***eted from a specific point in the DNA, this change is referred to as an *indel.* The length of an indel is between 1 and 10,000 base pairs and can include either insertions, deletions, or both.[9] Deletions occur with approximately three times the frequency of insertions.[10] Small indels (1–50 base pairs) are much more frequent than larger indels. The number of indels in the human genome is thought to be in excess of 2 million. Of these, more than 800,000 map to known human genes, affecting approximately 5.8% of all known human genes.[11] Consequently, indels are a significant source of genetic variation. Indels within coding and regulatory regions (promoters) are more likely to produce identifiable human phenotypes than indels in other parts of the genome.

Copy number variation (CNV): This refers to a segment of the genome 50 to 1 million base pairs that shows greater or fewer copies than the reference genome. Compared with SNPs and CNVs, this sort of variation has been more challenging to detect. As a result, the phenotypes associated with CNVs are still being defined. It appears that CNV is a relatively common form of genetic variation, especially those CNVs of relatively small size. Although CNV may be associated with

disease, not all CNVs are pathogenic. It appears that normal individuals have multiple small CNVs.[12] Larger CNVs are less common and are more likely to be pathogenic. Nevertheless, even relatively large CNVs are still common. Approximately 65% to 80% of individuals harbor CNVs of at least 100,000 base pairs and up to 10% harbor CNVs of at least 500,000 base pairs. Although CNVs are not always pathogenic, multiple illness phenotypes have been associated with CNVs, including Prader-Willi syndrome, Charcot-Marie-Tooth disease, Williams syndrome, and DiGeorge syndrome.[13,14]

Chromosome alterations: Chromosomal aneuploidy and translocation are detectable with microscopy and have been well characterized. Although balanced translocations in which the total amount of genetic material within the cell is unchanged may not be pathogenic, chromosomal abnormalities are frequent causes of genetic illness.

Because genetic variation within an individual occurs on multiple scales, all of these must be considered in order to understand the contribution of genetic variation to illness.

Genetic Variation and Protein Synthesis

If the genotype is a blueprint for the building of an organism, proteins are the important building blocks. Genetic variation produces changes in the blueprint and may produce important changes in the protein building blocks. Proteins structure may be altered by changes in the amino acid sequence, altered splicing, and early termination. Genetic variation may also affect rates of protein synthesis or change protein stability. Although neither of these mechanisms alter protein structure, they may produce important changes in the quantity of proteins present within a cell or secreted by a cell. Because protein function is dependent on both structure and concentration, any of these changes may have profound effects on the phenotype.

Although the purpose of our DNA is to encode proteins, only about 1% of the genome is dedicated to this purpose. Some of the noncoding portions of the genome serve regulatory functions, but little is still understood about a large portion of the noncoding DNA. Genes themselves contain both coding regions (exons) and noncoding regions (introns). On average, each gene contains 8.8 exons and 7.8 introns.[15] During RNA processing, the introns are removed and the remaining pieces of RNA are spliced together so that an intact protein may be transcribed from the messenger RNA. The location of a genetic variant (eg, SNP, CNV) is the primary determinant of the effect that will be produced by the variant.

Depending on where it occurs, an SNP can have different effects on protein levels and protein function. SNPs that occur in promoter regions of a gene may alter the rate of protein synthesis. The availability of mRNA from a given gene may be changed if an SNP alters the rate of RNA degradation. Increased RNA degradation would diminish protein synthesis while decreased RNA degradation could be expected to result in increased protein synthesis. SNPs occurring in introns can alter post-translational processing of the nascent protein, resulting in different protein splice variants. Many proteins have several splice variants that show differing levels of function. Indeed, it appears that splice site variation may be responsible for a

significant portion of the burden of human disease.[10]

SNPs that occur within exons may be silent if they do not produce a change in the amino acid encoded by a codon (synonymous SNPs) or they may alter protein function if they result in substitution of a different amino acid within the protein sequence (nonsynonymous SNPs). If a nonsynonymous SNP changes an amino acid codon to a stop codon, protein synthesis undergoes early termination. Because the gene is only partially transcribed, the resulting protein is likely to function poorly, if at all.

Indels can alter protein function by many of the mechanisms indicated earlier. Indels may also produce frameshift mutations. Amino acids in a protein are encoded by a series of nucleotide triplets (codons) in the DNA. If an indel disrupts one of these triplets by inserting or deleting an amino acid, the reading frame of all subsequent nucleotides is altered. In addition to changing many of the amino acids encoded after the mutation, frameshift mutations frequently result in an early stop codon causing early termination of protein synthesis.

Copy number variations and chromosomal alterations (eg, aneuploidy) are associated with a variety of disease states. Although the phenotypes produced by chromosomal alterations have long been recognized, the mechanism by which these large-scale changes in genome structure produce disease is not yet fully understood. An explanation to account for a portion of the observed phenotypic changes is that these events alter "gene dosing," with the result that certain gene products (proteins) are increased or decreased compared with the normal phenotype. Experimental evidence from several model organisms indicates that there is a correlation between gene copy number and mRNA levels.[16,17] A number of human genes that produce dosage-sensitive phenotypes have been identified.[18] Although this is an attractive mechanism for explaining the effects of copy number variations and chromosomal alterations, other effects may be important.

Finally, although epigenetic changes in DNA (methylation, histone modification, etc.) are beyond the scope of this discussion, these phenomena can produce important changes in phenotypes. Although many epigenetic traits are not heritable, some are transgenerational and will alter the phenotype of offspring. Such epigenetic changes may help to explain a portion of complex traits that are not easily understood in terms of classical genetics.

Developmental Timing of Mutations and Consequences

All mutations result from replication errors or DNA damage that is unrepaired or incorrectly repaired. In the latter case, environmental factors that injure DNA increase the risk of mutations. Changes in the sequence and structure of DNA can occur in germ cells or somatic cells. Depending on the cell type in which a mutation occurs, the ramifications for that mutation are quite different. Mutations inherited through the germline are transmitted to all the somatic cells of the offspring. In contrast, de novo mutations in somatic cells are transmitted only to the progeny of the original cell in which the mutation first occurred. Because somatic mutations do not involve germline cells, they are not inherited.

Mutations Occurring in Germline Cells (Prezygotic Mutations)

On average, every human being inherits approximately 60 new SNPs from their parents, although this figure may vary widely among individuals.[19] These inherited mutations occur in the germ cells of the parents and are transmitted to their offspring. Although somatic cell mutations may have serious consequences for an organism, only germline mutations have a long-term effect on population fitness. The frequency and type of mutation are influenced by gender and age of the parents. Germline SNPs increase sharply with paternal age, with approximately two new mutations per year.[20] Consequently, a 40-year-old father will carry approximately twice the number of germline SNPs as a 20-year-old father. The effect of age exerts a much smaller influence on increasing maternal germline SNPs. Approximately 95% of the variation in de novo SNPs among offspring is attributable to paternal age effect. Similarly, de novo copy number variations also correlate strongly with paternal age.[21] Increases in paternal age have been associated with an increased risk of autism, schizophrenia,[22] neurofibromatosis,[23] achondroplasia, and Apert syndrome among others.[24] Because humans have a long life relative to other species, the effects of paternal age may play a larger role in humans than in shorter-lived animals.

In contrast, maternal age correlates strongly with the risk of chromosomal structural mutations such as aneuploidy and chromosomal nondisjunction errors. In the past, because these large-scale events were detectable with light microscopy, the effect of maternal age on germline mutations was more readily appreciated compared with the effect of paternal age. Several disorders caused by chromosomal nondisjunction are frequently encountered in the critical care setting, including Down syndrome (trisomy 21), Klinefelter syndrome, Turner syndrome (monosomy X), Edward syndrome (trisomy 18), and Pautau syndrome (trisomy 13).

Mutations Occurring in Somatic Cells (Postzygotic Mutations)

Somatic cell mutations (those mutations that do not arise in germline cells) are not inherited from parents. These mutations can arise at any time during the life span of an individual. Human cells undergo trillions of cell divisions during the normal life span, with each division constituting a risk for somatic mutation. Somatic cell mutations that occur early in embryogenesis may become widespread through the organism leading to mosaicism. Recent evidence suggests that early fetal somatic cell mutations lead to substantial genetic variation within different tissues from the same individual.[25] Unlike germline mutations, which must result in a viable organism in order to be manifest, somatic cell mutations must only be compatible with producing a viable cell. Consequently, the spectrum of somatic cell mutations is broader than germline mutations.

Most somatic mutations are harmless; however, when one of these mutations causes a cell to escape from normal mechanisms regulating its growth and survival, the phenotype of this mutation may be cancer, which is the clonal expansion of a single abnormal cell. Usually, more than one mutation is required before a clone of cells fully escapes from normal biological regulation. The initial mutation may result

in a precancerous condition, which becomes cancer when one or more subsequent mutations permit the cell clone to escape fully from normal regulation. An example of this stepwise progression is adenomatous polyps of the colon that pose a risk for progression to colon carcinoma.[26] Because the accumulation of somatic mutations increases over the lifetime of an individual, the risk of developing cancer also increases as one ages.

Mutations in over 350 genes (approximately 1.6% of all genes) have been associated with an increased risk of cancer.[27] In more than 90% of these genes, the mutation is dominantly acting, which means that mutation of only one allele can contribute to cancer development. Many of these mutations operate quite differently from each other, which is consonant with the recognition that cancer may be caused by multiple molecular derangements. Scientists have discovered the genetic basis for many pediatric cancers including neuroblastoma, many leukemias, and brain stem medulloblastoma, among others.[28-30] Understanding of these derangements has suggested novel therapeutic targets, many of which are highly specific. Consequently, identification of the genetic mechanism of a particular cancer may be of paramount importance in selecting the optimal therapy.

Genetic Variation in Mendelian and Complex Traits

Human genetic traits may be classified as monogenic or complex, although there is often overlap between these two categories. Monogenic traits are those in which the phenotype is strongly influenced by a single gene. These traits follow Mendelian inheritance patterns and are the basis of "classical" genetics. Complex traits refer to phenotypes that are influenced by multiple genes. As the sequence and structure of the genome have been explored, it has become increasingly apparent that monogenic traits are relatively uncommon and that complex traits in which more than one gene influences a phenotype are more frequently encountered. Many commonly encountered illnesses that are phenotypes of complex traits include obesity, heart disease, hypertension, schizophrenia, Alzheimer disease, sepsis, and epilepsy, to name only a few. When several genetic loci contribute to the phenotype, the relative strength of each contribution must be determined in order to understand the disease phenotype.[31] Often, only a limited amount of the heritable component of a complex trait may be identified, which further complicates the understanding of the genetic basis for complex disease phenotypes. The power of genetic studies to detect disease-genotype associations is further impaired by the need to correct for multiple hypothesis testing, discussed in the following section.

High-Throughput Technologies—the Good and the Bad

Modern analysis of DNA and RNA relies heavily on high-throughput technologies in which thousands of chemical analyses are conducted in parallel. Such technologies are intensively reliant on computational data analysis and data management. High-throughput technologies have been used with great success in

DNA sequencing and in quantitating gene expression. The appeal of being able to conduct thousands of experiments at the same time is obvious: It is highly efficient. With some approaches, it is possible to assess the entire human genome in a single experiment consisting of thousands of individual analyses. When multiple analyses are conducted on the same sample, the analysis must adjust for multiple comparisons. Careful statistical analysis with attention to robust correction for multiple testing is essential to reduce the probability of false-positive results (type I error). Such adjustments come at a price. These statistical corrections decrease the power of the study and elevate the possibility of false negatives (type II error). This problem may be overcome by increasing the number of subjects in an investigation, but enrollment of additional subjects may be difficult and additional high-throughput analyses may be expensive. Because of these issues, high-throughput studies are at risk of being underpowered. Studies that lack sufficient statistical power are more likely to miss real associations between genetic variation and disease. When interpreting the results from high-throughput studies, it is important to keep in mind these caveats. Although high-throughput studies offer great potential because of their ability to survey the entire genome, this promise is accompanied by noteworthy challenges.

Genome-Wide Association Studies

Genome-wide association studies (GWASs) examine the association between SNPs and disease phenotypes. Such studies are possible because the HapMap project, which was completed in 2003, identified the frequency and location of SNPs in the human genome.[32] With the advent of high-throughput SNP genotyping technologies, GWASs have flourished. Since 2005, more than 2300 GWASs have been published,[33] providing insights into the heritable aspects of many human diseases. SNPs underlie a number of common monogenic and complex diseases.

SNPs occur once in approximately every 300 nucleotides, so there are approximately 10 million SNPs within the human genome. Fortunately, because a given SNP is usually in linkage disequilibrium with other SNPs, it is not necessary to test every SNP in the human genome to determine its association with a disease phenotype. Instead, in GWASs, a marker SNP is usually used as a surrogate for a genomic region that may contain hundreds of other SNPs. Because GWASs rely heavily on marker SNPs (called "tag" SNPs), an SNP that is found to be associated with a disease phenotype is often not the causative SNP. Instead, all that can be known with certainty is that the tag SNP is in linkage disequilibrium with the causative variant. This variant could be another SNP or could be a structural variant. Although this approach eliminates the need to test all 10 million SNPs within the genome, the greater the number of SNPs that are tested, the higher the resolution of the results. It is common for current SNP analyses to test more than 100,000 SNPs in each study subject.

Individuals of European ancestry are overrepresented in GWASs.[34] Because of the differences in SNP distributions in different ancestral populations, it is important to consider the populations examined in a GWAS before generalizing the results to other populations. Other issues must also be considered in interpreting GWASs. Because of the large number of genetic loci that are screened for their association with disease, GWASs have an increased risk of type II error (false-negative errors).

Unless a study is adequately powered, failure to find an association between a genetic locus and a disease may represent a false-negative finding. The high cost of GWAS analyses and the challenges of enrolling a large number of subjects constitute formidable hurdles to achieving sufficient power in GWASs.

Positive findings in a GWAS should be replicated in a separate investigation with a different group of patients (with appropriate attention to population structure of the new cohort). Positive findings may be replicated in another GWAS, or they may be replicated in a targeted analysis that tests only a small number of SNPs that are in linkage disequilibrium with the SNP identified in the original study. A targeted approach tests fewer SNPs, so the loss of power from multiple hypothesis testing is much less of a problem. Accordingly, it may be possible to enroll fewer patients and conduct a more cost-efficient study. Once the findings have been replicated, other challenges must be addressed such as determining the causative variant and determining the mechanism by which this variant causes disease susceptibility.

Although GWASs have great potential to expand the understanding of sepsis and other diseases commonly encountered in critical care, this promise is offset somewhat by the limited power of GWASs.[35] To overcome this obstacle requires the enrollment of large numbers of patients, which is a difficult and expensive undertaking in the critical care setting. Furthermore, many of the disease processes in critical care are likely to be caused by complex genetic traits, which are known to pose special challenges for GWASs. The promise of GWASs is great; however, a substantial investment in time and money may be necessary to begin to realize this promise.

Looking Toward the Future

Using information about a patient's unique genetic makeup to create an optimal care plan is the long-sought goal of personalized medicine. While progress has been made toward this goal, the full complexity of variation within the human genome is still being defined. Many human phenotypes are complex and involve contributions from multiple genetic loci, making this goal difficult to achieve. As clinicians gain a better understanding of the relationship between human genetic variation and states of health and disease, they will be presented with a host of opportunities to improve health care.

CHAPTER 84

Molecular Foundations of Cellular Injury

Apoptosis and Necrosis

Rohit Mittal, John D. Lyons, Craig M. Coopersmith

PEARLS

- Cell death is an important physiologic homeostatic mechanism critical for host survival.
- Apoptosis and autophagy are evolutionarily conserved processes.
- Alterations in the machinery driving apoptosis and autophagy play an important role in the pathogenesis of critical illness.
- Necroptosis appears relevant to a number of clinical disease processes, although its role in critical illness is still being defined.
- Targeting the mechanisms of cell death may play an important role in the future treatment of human disease and critical illness.

Cell Death

Each day, the human body produces and eradicates billions of cells, a rate of cell death of nearly 1 million per second.[1] Cell death is therefore an integral homeostatic process to the survival of a living organism, but when perturbed it can also lead to sickness or mortality. Cell death, both physiologic and pathologic, occurs through distinct mechanisms, including apoptosis, necrosis, necroptosis, and autophagy.[2] These mechanisms are regulated by molecular signals that culminate in morphologically different modes of cell death.

Apoptosis is a programmed form of cell suicide that morphologically results in nuclear condensation (pyknosis) and fragmentation (karyorrhexis), organelle shrinkage and removal, and cytoplasmic blebbing without alterations in the integrity of the cellular plasma membrane.[1,3,4] As cells undergo apoptosis, they shrink and form apoptotic bodies, which are subsequently engulfed by nearby phagocytic cells

and cleared by lysosomes.[5] Orderly DNA fragmentation is identifiable on electrophoretic gels as a characteristic "ladder" pattern. Apoptosis is an evolutionarily conserved process that is vital during fetal development in shaping limbs, the intestinal tract, and other vital organs and persists throughout life in tisses undergoing high cell turnover. Notably, because cytosolic contents are not released into the interstitial space, apoptosis is not accompanied by an inflammatory response.

Unlike the orderly process of apoptosis, necrosis is a form of cell death due to extrinsic stress or damage, resulting in nuclear and organelle swelling and eventual cell lysis.[2] Morphologically, a necrotic cell swells and has a random pattern of DNA and cellular fragmentation, which is a stark contrast to the controlled shrinkage of an apoptotic cell.[1,2,6] As cell membranes break down, intracellular contents are released into the interstitial space and may be detected by neighboring immune cells, triggering an inflammatory host response. These molecules or fragments are referred to as damage-associated molecular patterns (DAMPs).[6-8]

Though the process of necrosis has traditionally been considered accidental or uncontrolled, forms of regulated necrosis or "necroptosis" have recently been described.[9-11] Necroptosis is similar to apoptosis in that it is a receptor-mediated process driven by highly regulated intracellular signaling pathways. However, an important distinction from apoptosis is that necroptosis results in cell permeabilization, swelling and release of intracellular contents that more closely resemble traditional necrosis.[9,10] As with more "classical" forms of necrosis, the release of intracellular contents associated with regulated cell death in necroptosis is highly inflammatory.[7]

Similar to apoptosis, autophagy is a conserved cell death pathway; however, autophagy is a mechanism of cytoprotection that takes place during states of cellular stress.[4] This process involves sequestration of cellular contents within vesicles called autophagosomes, which then proceed to lysosomal degradation.[3] In physiologic situations, this highly regulated process serves to maintain homeostasis within a cell by eliminating excessive, dysfunctional, or wasteful organelles and allowing their catabolic end products to be recycled to meet the energy needs of a cell.[12] Although this is an adaptive cytoprotective response, if it persists uncontrolled, the end point is loss of vital cell components and eventual cell death.

Mechanisms of Cell Death

Apoptosis is regulated by a complex and conserved set of pathways (Fig. 84.1). The process is initiated either by an extrinsic (receptor-mediated) pathway or an intrinsic (mitochondrial) pathway. The extrinsic pathway is regulated through Fas ligand, tumor necrosis factor TNFα, or TNF-related apoptosis-inducing ligand (TRAIL) signaling via their respective receptors (Fas, TNFR1, TNFR2, TRAIL-R1, TRAIL-R2) on the cell surface. This leads to activation of cysteine aspartyl protease (caspase)-8 intracellularly.

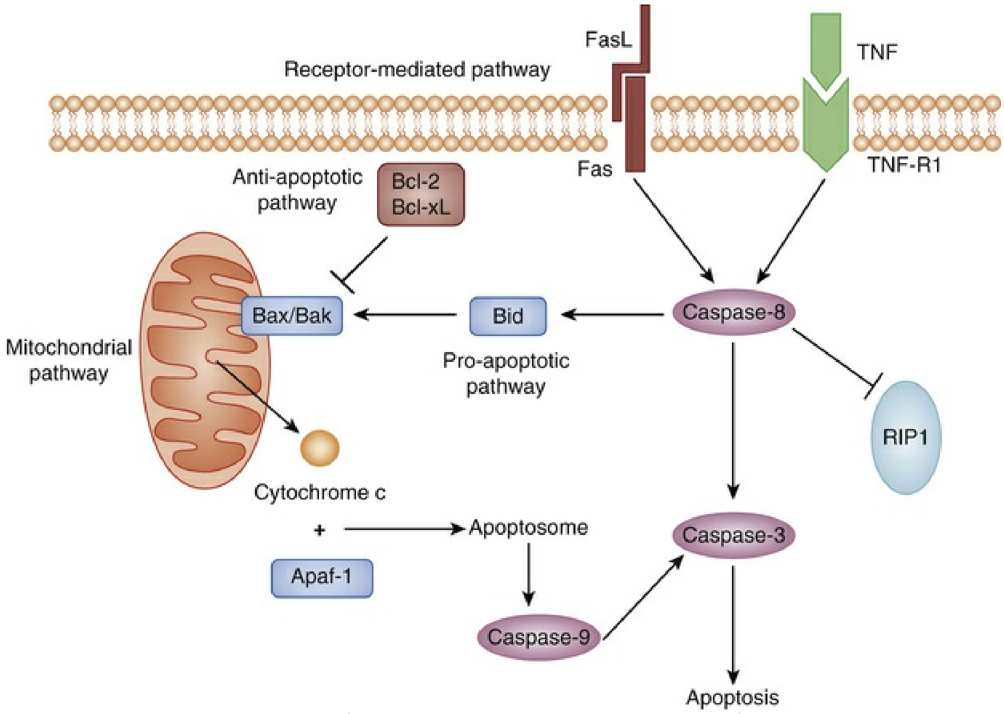

FIG. 84.1 Diagram of complex and conserved set of pathways that regulates apoptosis.

In contrast, the intrinsic pathway is regulated through intracellular mitochondrial signaling. In this pathway, DNA damage from reactive oxygen species, radiation, chemotherapy, or other pathologic insults results in the release of cytochrome c from the mitochondria into the cytoplasm, which allows apoptotic protease activating factor (APAF)-1 to interact with adenosine triphosphate (ATP) to form an apoptosome, which triggers caspase-9 activation[13] (see also Chapter 80). Within the mitochondrial pathway, the Bcl-2 family of molecules plays a critical role. This group of proteins includes more than 20 proapoptotic and antiapoptotic molecules, many of which physically interact with each other. Their primary function appears to be regulation of cytochrome c release from the mitochondria with proapoptotic family members promoting and antiapoptotic members suppressing its release. Prototypical proapoptotic proteins in this family include Bax and Bak, whereas prototypical antiapoptotic proteins include Bcl-2 and Bcl-xL[3,13-16]

Caspase-8 and caspase-9 ultimately both converge on the final common pathway of apoptosis, via induction of the death effector caspase-3, ultimately leading to the death of the cell. Additionally, activation of caspase-8 facilitates crosstalk between both pathways via activation of Bid.[16,17]

Necroptosis is also initiated via a receptor-mediated pathway (Fig. 84.2) via intracellular signaling primarily through the serine-threonine protein kinases receptor-interaction proteins 1 and 3 (RIP1 and RIP3). When caspase-8 activity is compromised, binding of TNFα (or other extrinsic death ligands) to its cell surface receptors allows RIP1-RIP3 interaction and phosphorylation, leading to RIP3-mediated phosphorylation of mixed lineage kinase domain-like protein (MLKL).[18-22] Activated MLKL is then trafficked to the cellular membrane, which it then permeabilizes, facilitating cell swelling, calcium influx, and necrotic cell death.[23,24] Several initiating factors have been shown to be capable of inducing necroptosis under varying cellular conditions, including TNFα, Fas, IFNy, and signaling via

TLR3 and TLR4.[18,19,25,26]

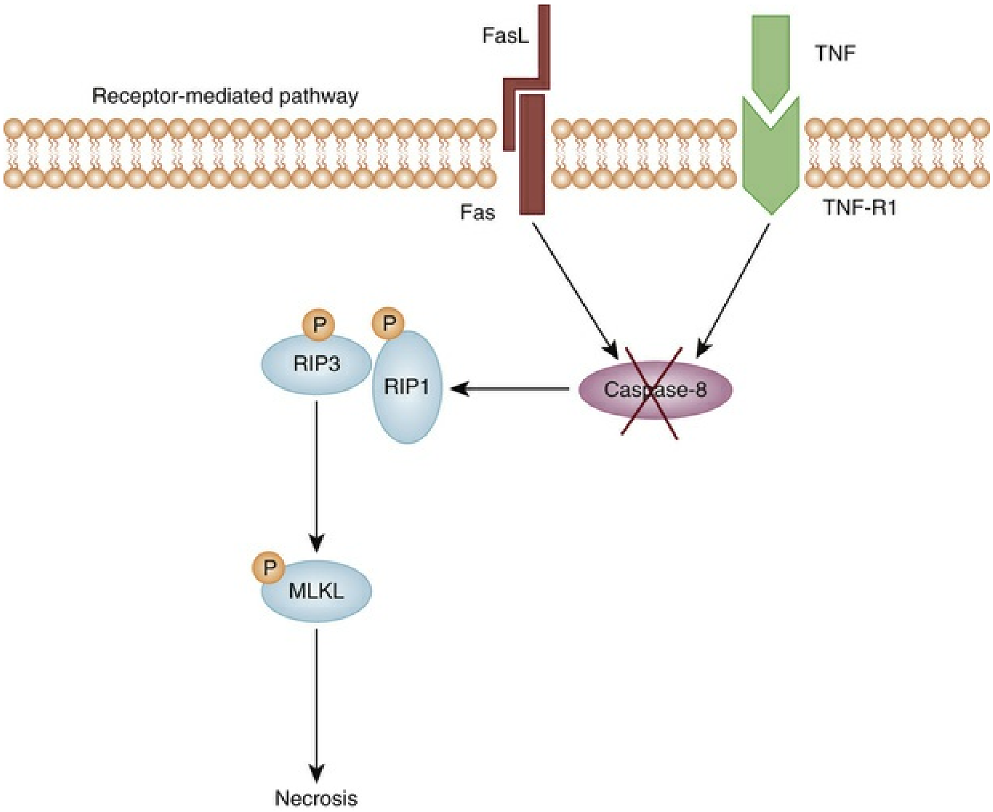

FIG. 84.2 Diagram of a receptor-mediated pathway that initiated necroptosis.

Research has begun to unravel the mechanisms that lead to autophagosome formation in autophagy. Although autophagy serves an important adaptive role during stress, excessive cellular degradation can lead to or propagate states of disease. During states of stress, autophagy can be induced via interruptions in the interaction between the antiapoptotic protein Bcl-2 or Bcl-xL and beclin-1, a protein important for autophagosome formation and signaling.[3] The crosstalk between the machinery driving autophagy is complex and byproducts of the autodegradation process, such as autophagy protein (Atg)-5, can stimulate cytochrome c release and apoptosome activation via the intrinsic pathway or though Atg-5 and caspase-8 interactions resulting in a proapoptotic complex.[3,4,27]

How Do Cellular Death Mechanisms Propagate Critical Illness?

Human Studies

The role of cell death, especially apoptosis, in critical illness has become increasingly understood. In 1999, Hotchkiss and colleagues showed that septic patients who died in a surgical intensive care unit and underwent immediate autopsy had markedly increased lymphocytic and gut epithelial apoptosis.[28] In addition, necrosis was

detectable in the liver a third of the time but was minimal or absent in all other tissues examined. Similar findings have been shown in both neonates and pediatric patients with sepsis.[29,30] Subsequently, Takasu and coworkers examined what role cell death might play in sepsis-induced cardiac and renal dysfunction and noted little evidence of cardiac myocyte death.[31] Although there was some evidence of necrosis in renal tissue, the extent of overall cellular death noted did not explain the degree of organ dysfunction. Liver autophagy is also increased in autopsy studies of septic patients with sepsis.[32] Increased lymphocyte apoptosis in septic patients has also been demonstrated to be associated with an increase in active caspase-3 activity. Further, B and $CD4^+$ T lymphocytes are disproportionately lost in septic patients,[33] and B and $CD4^+$ T-lymphocyte apoptosis is caspase-9 dependent, with the degree of cell death greater the longer the patient is septic. Antigen-presenting dendritic cells are also decreased in spleens of septic patients.[34] Notably, spleen biopsies from patients who died in a surgical intensive care unit demonstrated significant immune cell loss, including decreased populations of CD4+ and CD8+ T cells as well as biochemical findings of immune suppression including impaired T-cell effector function and cytokine production.[35] In contrast, apoptosis is significantly decreased in bronchoalveolar lavage (BAL) macrophages in septic patients compared with nonseptic controls,[36] associated with lower levels of Bcl-2 than in control patients. Minimal macrophage necrosis has been detected in BAL fluid. In addition, apoptosis is decreased in neutrophils in septic patients through up-regulation of tyrosine phosphorylation by circulating mediators.[37]

Increased apoptosis is also seen in circulating T lymphocytes of patients following blunt trauma or burn injury,[38,39] and increased apoptosis in circulating T cells of trauma patients correlates with T-cell anergy. In contrast, neutrophil apoptosis is low in BAL fluid from patients with acute respiratory distress syndrome (ARDS) as well as those at risk for ARDS.[40,41] Notably, in vitro human polymorphonuclear leukocytes from healthy volunteers have less apoptosis when incubated with BAL fluid from ARDS patients as compared to BAL fluid from healthy controls. Further evaluation of this antiapoptotic effect on normal neutrophils showed it to be highest during the early stages of ARDS with subsequent decreases over time. The change in apoptotic response to BAL fluid from ARDS patients correlates with levels of granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor.[42] Soluble Fas ligand is also higher at the onset of ARDS in patients who eventually die, and BAL fluid from patients with ARDS induces a Fas-dependent apoptosis in distal lung epithelial cells, whereas BAL fluid from patients at risk for ARDS but without the disease does not have an effect on distal lung epithelial cell death. BAL fluid also has elevated concentrations of the apoptosis-related molecules perforin, granzyme A, and granzyme B in critically ill patients with early ARDS compared with those not having lung injury or late ARDS.[43]

Animal Studies

Similar to human autopsy studies, apoptosis is primarily localized to lymphocytes, dendritic cells, and the gut epithelium in animal models of sepsis. In both cecal ligation and puncture (CLP), a murine model of fecal peritonitis and *Pseudomonas aeruginosa* pneumonia, maximal lymphocytic and intestinal apoptosis occur 24 hours after the onset of septic insult.[44-47] Both intrinsic and extrinsic pathways play a role in

sepsis-induced apoptosis, and pathways differ depending on which model of sepsis is examined.[48] Animals with gene specific knockouts of multiple members of the proapoptotic Bcl-2 family members (mitochondrial pathway) or Fas-associated death domain transgenic mice (receptor mediated) demonstrate significant decreases in sepsis-induced splenocyte apoptosis.[49,50] Although apoptosis, whether initiated by the mitochondrial or the receptor-mediated pathway, converges into a single common pathway mediated by caspase-3, it should be noted that there are likely alternate pathways that are independent of caspase-3 given that caspase-3 knockout mice exhibit only a small degree of apoptosis.[51]

Increased lymphocytic apoptosis appears to be detrimental to survival in sepsis. Overexpression of Bcl-2 in transgenic mice in either T lymphocytes or B lymphocytes markedly improves survival in multiple strains of inbred mice subjected to CLP.[51,52] Similar increases in survival have been shown in mice where the proapoptotic Bcl-2 family member Bim has been knocked out.[50] Administration of the polycaspase inhibitor N-benzyloxycarbonyl-Val-Ala-Asp(O-methyl) fluoromethyl ketone (z-VAD) or the caspase-3 specific inhibitor M-971 results in similar improvements in outcome.[52,53]

The mechanisms that account for worse outcomes with increasing lymphocytic apoptosis appear to involve immunosuppression. Although immunosuppression in sepsis is multifactorial, the ongoing loss of immune effector cells in both the innate and adaptive compartments likely plays a significant role. In addition to the loss of cells, there is an up-regulation of T regulatory cells and myeloid-derived suppressor cells.[53] This up-regulation of immunosuppressive cells appears to be driven in part by the production of IL-10, an antiinflammatory, immunosuppressive cytokine. Notably, adoptive transfer of necrotic cells improves survival in septic animals, and this benefit is lost if IFNγ production is blocked.[54] In contrast, apoptotic cells not only increase mortality but they also prevent IFNγ production. Interestingly, a preexisting immunosuppressive state may alter the immune apoptotic response. Septic mice with preexisting pancreatic adenocarcinoma tumors have a higher mortality when compared to noncancer septic mice,[55] and the presence of malignancy not only impairs tumor-specific immune responses but also pathogen-specific responses as well resulting in a state of generalized immune suppression.[56] Notably, either lymphocyte overexpression of Bcl-2 or germline deletion of Bim in cancer mice results in elevated mortality, contrary to what is seen in septic hosts that were previously healthy.[57]

Prevention of gut epithelial apoptosis also improves survival in preclinical models of sepsis as overexpression of Bcl-2 in gut epithelium decreases mortality in mice subjected to CLP or *P. aeruginosa* pneumonia.[47,58] In addition, giving systemic epidermal growth factor (EGF) normalizes intestinal Bid expression and apoptosis and mortality following CLP,[59,60] and these protective effects appear to be modulated through the intestinal epithelium as similar results are seen if EGF is selectively overexpressed in intestinal enterocytes.[61-63] Notably, the immune system directly impacts apoptosis in the intestinal epithelium in critical illness. $Rag^{-/-}$ mice, which lack lymphocytes, have a fivefold higher level of gut epithelial apoptosis after CLP compared to WT mice, and adoptive transfer of CD4+ T cells in $Rag^{-/-}$ mice restores apoptosis back down to WT levels.[64]

Respiratory epithelial cells are resistant to apoptosis when exposed to *P. aeruginosa*, undergoing cell death in vitro.[65] However, *P. aeruginosa* pneumonia

induces respiratory epithelial apoptosis in mice through activation of the Fas/Fas ligand system,[66] and respiratory apoptosis appears to be essential for survival in this study, with rapid sepsis-induced mortality in Fas or Fas ligand–deficient mice that lack bronchial apoptosis. Alveolar and bronchiolar apoptosis are also present in rats with *Streptococcus sanguis* or *Streptococcus pneumoniae* type 25 pneumonia.[67,68] Lung apoptosis has also been demonstrated following CLP in multiple mouse strains although recently it has been questioned whether CLP causes lung injury.[69] Acute lung injury causes increased death in multiple cells within the lung, and intratracheal injection of lipopolysaccharide (LPS) induces apoptosis in alveolar cells, neutrophils, and macrophages.[68,70] This process is associated with up-regulation of Fas in alveolar and inflammatory cells, and lung injury can be blocked by administration of an anti-Fas antibody. Both epithelial and endothelial apoptosis also occur in the lung in a rat trauma-hemorrhagic shock model in a caspase-3 dependent (epithelial) and independent (endothelial) manner.[71]

Although liver apoptosis is not noted in human autopsy studies of sepsis, there is an increase in murine hepatocyte apoptosis following infection with *Listeria monocytogenes*.[72] Liver apoptosis is greatest at the edge of microabscesses and is independent of endotoxin, Fas, and nitric oxide. Extensive hepatocyte apoptosis is also seen in animal models of trauma/hemorrhage and is dependent on the severity of shock induced with increasing apoptosis correlating with duration of shock.[73,74] In addition, apoptosis is only seen following resuscitation, and the introduction of IL-6 at the time of resuscitation completely prevents trauma hemorrhage–induced apoptosis.[74] Apoptosis of hepatocytes is also seen in animal models of thermal injury.[75] Apoptosis is also increased in murine granulocytes after CLP through a TNFα-dependent pathway.[76]

Necroptotic pathways of cell death have been implicated in preclinical models in a number of clinical disease processes including sepsis, viral infections, stroke, myocardial infarction, pancreatitis, acute kidney injury, and inflammatory bowel disease.[26,77-81] Notably, deletion of RIP3 results in a substantial survival advantage in mice undergoing CLP.[82] When mice deficient in apoptosis-inhibitors are subjected to influenza infection, they suffer significant lung epithelial cell destruction via RIP3 and display mortality compared to WT controls.[83] Further, mice deficient in the apoptotic adaptor Fas-associated death domain (FADD) develop a severe and erosive colitis, similar to that seen in Crohn colitis, and like human colitis, the inflammation in FADD-deficient mice is largely TNFα driven. Interestingly, inflammatory colon lesions in these animals are prevented by deletion of the necroptotic protein RIP3.[58] TNFα-dependent skin conditions can also be cured in animals by deleting necroptotic proteins, suggesting that these pathways may be involved in a host of human disease that prominently feature TNFα as a mediator.[84,85] Beyond tissue-specific processes, deletion of RIP1 has been shown to cause perinatal lethality associated with severe systemic inflammation at birth with cell necrosis via RIP3-MLKL.[86]

There is a growing body of literature characterizing the role of autophagy in animal models of critical illness. Hepatocytes have a decline in autophagy in the later stages of sepsis following CLP,[87] and mice treated with carbamazepine have a more complete activation of the autophagic response and attenuated liver injury following CLP.[88] Similarly, septic animals have an attenuated autophagic response in renal tubules following sepsis.[89] In the heart, rapamycin treatment induces

autophagy and restores CLP-induced cardiac dysfunction.[90] Autophagy may also play a role in immune dysfunction as T cells in septic mice have decreased autophagy (in addition to increased apoptosis).[91]

Globally, the balance of cell production and loss is critical to homeostasis, and normal physiologic cell death plays a vital role in maintaining this balance. However, cell death is also centrally implicated in multiple human diseases and can result in significant pathology when left unchecked. Therapeutic agents that target and manipulate cell death pathways may be attractive targets to treat critically ill patients. However, it is important to note, though, that blocking one pathway of cell death may simply trigger another. Necroptosis was first identified in cell cultures with inhibited apoptotic machinery, and animal models have confirmed that blocking apoptosis can unleash necrotic cell death.[18,20,92] In vivo myocardial infarction modeling has also indicated that outcomes are most improved not by limiting just apoptosis or necrosis but by limiting both simultaneously.[93] If novel drug therapies are to one day treat human disease and critical illness, a thorough and complete understanding of the intricate, interconnected pathways of cell death must first be established.

CHAPTER 85

Common Endocrinopathies in the Pediatric Intensive Care Unit

Ofer Yanay, Jerry J. Zimmerman

PEARLS

- Cortisol, produced in the adrenal *zona fasciculate,* is a key mediator of the stress response and influences much more than hemodynamics and inflammation by modulating the transcription of perhaps 20% of the entire genome.
- Relative adrenal insufficiency and critical illness–related corticosteroid insufficiency are poorly understood concepts in terms of both pathophysiology and therapeutic intervention.
- Critical illness hyperglycemia is the result of inflammation-mediated increased endogenous glucose production and decreased utilization secondary to insulin resistance.
- Although the evidence on glycemic control and its benefits is controversial, it is difficult to ignore the convincing association that exists between hyperglycemia and morbidity and mortality, as well as the results of initial trials reporting a significant decrease in mortality when critically ill adult and pediatric patients were maintained euglycemic.
- Sick euthyroid syndrome, common among critically ill patients, is characterized by a rapid decrease in T3 and variable increase in rT3 that appears to be proportional to the intensity of illness severity and concentration of TNF-α.

As discussed in Chapter 81 the endocrine system is closely aligned with the neurogenic and inflammatory systems, particularly as an aspect of the stress response. Multiple servo feed-forward and feed-back signaling normally provide precise control over this integrated system, but critical illness and its treatment may generate unique endocrinopathies. In addition, the intensivist may encounter patients with primary deficiency or excess endocrinopathies as the underlying cause of critical illness.

Hypothalamic-Pituitary-Adrenal Axis

A schematic overview of the classic regulation of cortisol synthesis and secretion is provided in Fig. 85.1.

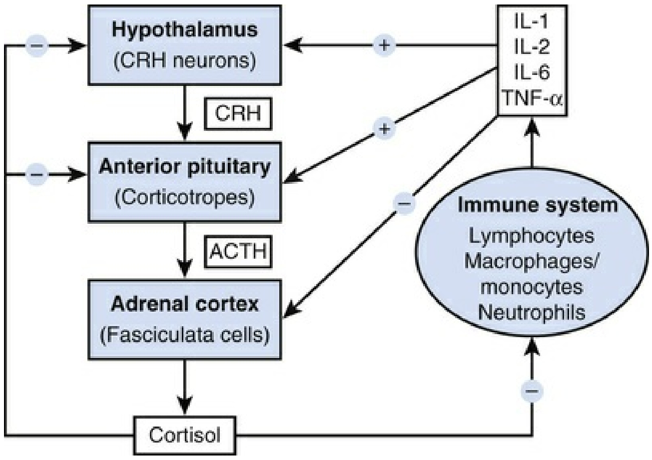

FIG. 85.1 Signaling for hypothalamic-pituitary-adrenal axis.[1]

A variety of stimuli converge on the paraventricular nucleus of the hypothalamus, resulting in release of corticotropin-releasing hormone (CRH).[2-4] Similar stimuli also increase release of antidiuretic hormone (ADH, arginine vasopressin).[5] ADH and aldosterone, generated via activation of the renin-angiotensin-aldosterone axis,[6] control salt and water balance as discussed in Chapter 73. As summarized in Table 85.1, angiotensin II also mediates a number of other neurogenic-endocrine-inflammation–related actions relevant to critical illness.

TABLE 85.1
Activities of Angiotensin II

- Increases systemic vascular resistance and blood pressure
- Stimulates aldosterone release
- Increases plasminogen activator inhibitor–1, promoting prothrombotic state
- Enhances thirst and salt craving
- Increases antidiuretic hormone, adrenocorticotropic hormone, and norepinephrine release
- Facilitates Na reabsorption at proximal convoluted tubule
- Stimulates renal afferent/efferent vasoconstriction
- Increases nuclear transcription factor NF-κB, resulting in increased proinflammatory cytokine production
- Mediates cardiomyocyte hypertrophy

CRH is transported via hypophyseal portal capillaries to the anterior pituitary, facilitating the production of pro-opiomelanocortin, a 239 amino acid peptide that includes primary protein sequences for adrenocorticotropic hormone (ACTH), beta-lipotropin, beta-endorphin, and melanocyte-stimulating hormone. The hypothalamic-pituitary stalk is susceptible to shear injury, and this may be associated with long-term pituitary dysfunction following head trauma.[7] ACTH is transported by the blood to the *zona fasciculata* of the adrenal gland, where it binds to type 2 melanocortin receptors (MC2R). Bioinactive ACTH (the p.R8C ACTH mutant that lacks bioactivity but conserves immunoreactivity) has recently been demonstrated as a cause of adrenal insufficiency.[8] Familial cortisol deficiency is a

lethal condition associated with hypoplastic adrenal glands and is caused by another mutation in the *MC2R* gene.[9] Single nucleotide polymorphisms in *MC2R* may be responsible for some of the variability in cortisol response to pediatric critical illness.[10] *MC2R* is a seven-transmembrane domain protein coupled with G proteins that uses intracellular cyclic adenosine monophosphate signaling to modulate adrenal steroidogenesis.[11]

During critical illness, activation of the HPA axis frequently reflects activation of the systemic inflammatory response syndrome (eg, by interleukin-6).[12] Interleukins 1, 2, and 6 are generally thought to stimulate cortisol production, whereas tumor necrosis factor–alpha (TNF-α), macrophage inhibitory protein (MIP), and corticostatin, a peptide defensin with anti-ACTH activity, are generally considered to be inhibitory for cortisol production.

Cortisol Biochemistry

A schematic overview of the biosynthesis of adrenal cortical hormones is summarized in Fig. 85.2.[13]

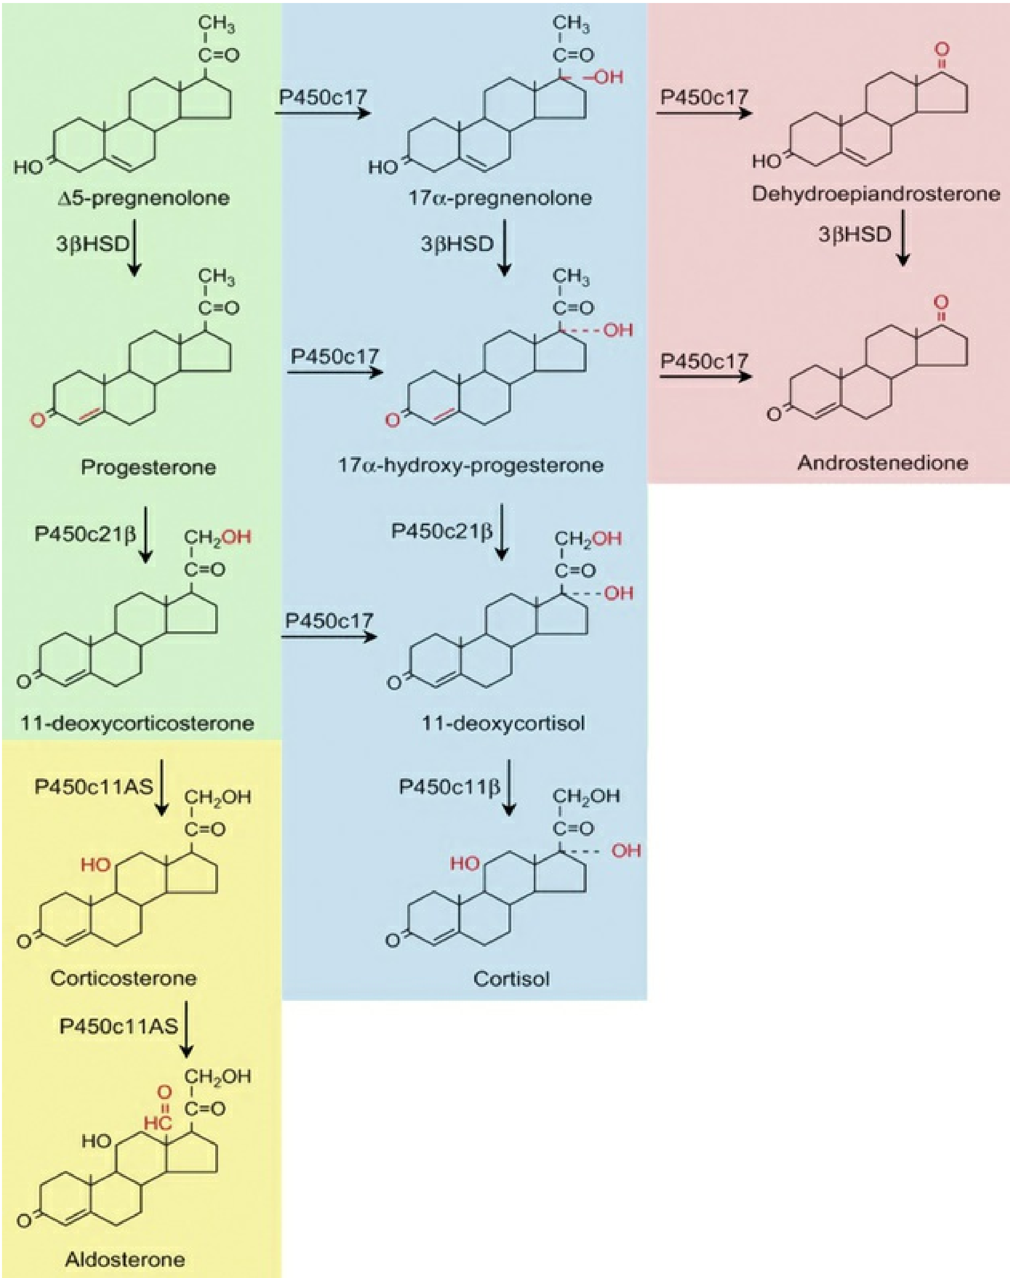

FIG. 85.2 Biosynthetic pathways for adrenal cortical hormones. Reactions highlighted in yellow are unique to the zona glomerulosa. Reactions highlighted in blue occur in the zona fasciculata. Reactions highlighted in green are seen in both the zona glomerulosa and reticularis. Reactions highlighted in pink are largely confined to the zona reticularis. Structural changes produced in each reaction are shown in red. (From Goodman HM. Basic Medical Endocrinology. Boston: Elsevier; 2009, p 65.)

Synthesis of pregnenolone from cholesterol represents a rate-limiting step in cortisol production and requires both mobilization of cholesterol from storage depots, as well as a transfer to a specific cytochrome P-450 located on the inner mitochondrial membrane that catalyzes side chain cleavage.[14] The second rate-limiting step in cortisol production involves the conversion of 11-deoxycortisol to cortisol by the enzyme 11β-hydroxysteroid dehydrogenase, another specific cytochrome P-450 isoenzyme.[15] Generation of a unique hydroxyl group at carbon 11

is essential for cortisol-mediated antiinflammatory and glucose homeostasis functions. A diurnal rhythm of cortisol production is noted among healthy (but not critically ill) patients with peak cortisol production typically 0800 to 0900 and a nadir of cortisol production typically around midnight. Normal adrenal production of cortisol is approximately 9 mg/m^2/day. Stress production of cortisol may reach 200 to 300 mg/day, resulting in a plasma total cortisol concentration occasionally exceeding 60 μg/dL. Among critically ill patients, plasma cortisol–cortisone ratios increase due to an increase in 11β-hydroxysteroid dehydrogenase activity.[16] In addition, reduced cortisol breakdown, related to suppressed expression and activity of cortisol catabolic enzymes, contributes to hypercortisolemia and associated ACTH suppression.[17] If the latter is maintained during prolonged critical illness, adrenal lipid depletion and reduced ACTH-regulated gene expression may occur in conjunction with adrenal atrophy and insufficiency.[18] Hypercortisolemia in critical illness is correlated with severity of illness.[19] Mean and range of plasma cortisol concentrations as a function of age have been reported for normal children and may be found in Table 85e.1.[20]

TABLE 85e.1

Plasma Cortisol Levels as Function of Age

	2 Hr	7 Da	2 Wk–3 Mo	3 Mo–1 Yr	1 Yr–3 Yr	3 Yr–5 Yr	5 Yr–7 Yr	7 Yr–11 Yr	11 Yr–15 Yr

174 normal children were assessed at 0800-1000, unrestrained activity, random diets.

Cortisol concentrations as μg/dL.

Sippell WG, Dörr HG, Bidlingmaier F, et al. Plasma levels of aldosterone, corticosterone, 11-deoxycorticosterone, progesterone, 17-hydroxyprogesterone, cortisol, and cortisone during infancy and childhood. Pediatr Res. 1980;14:39-46.

Although the plasma half-life for cortisol ranges 80 to 115 minutes, biological duration of action of cortisol is approximately 8 hours. Cortisol is catabolized by reduction of the steroid nucleus C4-C5 double bond, reduction of the C3 ketone to a hydroxyl, oxidation of the C11 hydroxyl group, or conjugation of the C11 hydroxyl group with either sulfate or glucuronic acid. Cortisol exhibits mineralocorticoid activity approximately 1% that of aldosterone.

Actions of Cortisol

Cortisol is transported from the adrenal gland to various tissues via cortisol binding proteins, namely transcortin with high affinity but low capacity and albumin with low affinity but high capacity.[21] Transcortin with a molecular weight of 58,000 Da is a member of the serpin serine protease super family, with a plasma concentration of approximately 1 μM. Cortisol concentration is locally increased at sites of inflammation through degradation of transcortin by neutrophil elastase, as well as local upregulation of 11β-hydroxysteroid dehydrogenase.[22]

Cortisol diffuses through the plasma membrane binding to the glucocorticoid receptor (GCR), which is flanked by heat shock proteins for transport to the cell nucleus, where cortisol subsequently binds to glucocorticoid responsive elements.[23,24]

Commonly occurring GCR polymorphisms may explain individualized patient responses to corticosteroids.[25] Children with septic shock demonstrate a transient depression of GCR mRNA in their neutrophils[26] that may reflect an adaptive cortisol resistance response. On the other hand, septic patients may demonstrate a transient increased[27] or decreased[28] expression of GCR on mononuclear cells. Corticosteroid treatment induces expression of microRNA-124 that downregulates GCR-alpha with resultant modulation of antiinflammatory effects.[29] A common polymorphism of the GCR has been associated with posttraumatic stress disorder following critical illness.[30] Glucocorticoid receptors represent a potential drug target for treatment of severe inflammation and the consequences of excess endogenous or exogenous corticosteroid.[31]

Cortisol also affects nuclear migration of transcription factors NF-κB, as well as activator protein-1 (AP-1).[32,33] Ultimately, cortisol modulates the transcription of thousands of genes, perhaps 20% of the entire genome.[34,35] Although the majority of corticosteroid action is related to changes in gene transcription mediated through chromatin remodeling, corticosteroids also affect protein synthesis by decreasing the stability of messenger RNA. A number of inflammatory proteins appear to be regulated by this posttranscriptional mechanism.[34] Even with appropriate cortisol production by the adrenal gland, cortisol resistance syndrome can occur by multiple mechanisms including depletion of corticosteroid-binding globulins, activation of 11β-hydroxysteroid dehydrogenase, decreased glucocorticoid receptor density and activity, and elevated antiglucocorticoid compounds and receptors.[32,36,37]

Cortisol affects three general areas of physiology: immunity, metabolism, and hemodynamics.

Immunity[32,38-40]

Much of critical illness may involve disturbance of the balance between systemic inflammatory responses (SIRs) versus compensatory antiinflammatory responses (CARs).[41-43] As depicted in Fig. 85.3, cortisol biochemistry represents a key regulatory mechanism for virtually all aspects of antiinflammation.

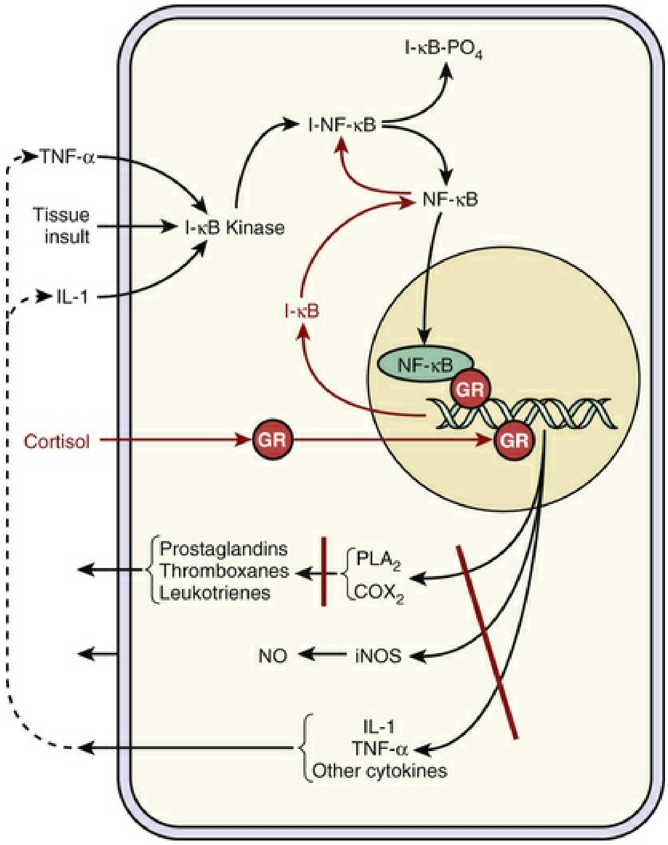

FIG. 85.3 Signaling for the antiinflammatory actions of cortisol.[13] (From Goodman HM. Basic Medical Endocrinology. Boston: Elsevier; 2009, p 80.)

In this respect, cortisol increases the synthesis of IκB, trapping NF-κB in the cytoplasm and effectively thwarting synthesis of a variety of proinflammatory mediators. Similarly, cortisol blocks NF-κB and AP-1 binding to appropriate DNA promoter regions. In addition, cortisol increases the production of annexin that inhibits phospholipase A_2, resulting in modulation of both cyclooxygenase and lipoxygenase inflammatory lipid pathways. Sepsis induces widespread immunosuppression.[44] Among septic children administered corticosteroids, further repression of gene networks related to adaptive immunity has been reported.[39]

Metabolism[45-48]

A schematic summary of the effects of cortisol on metabolism is displayed in Fig. 85.4.[13]

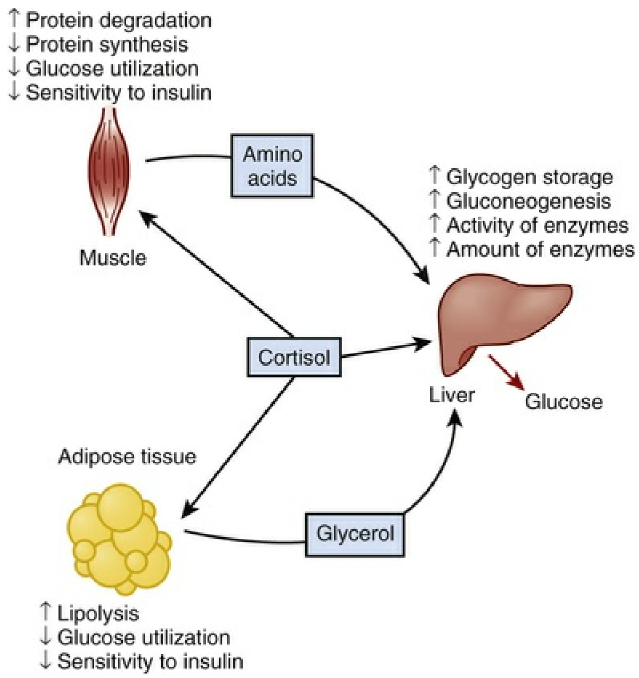

FIG. 85.4 Schematic overview of metabolic actions of cortisol. (From Goodman HM. Basic Medical Endocrinology. Boston: Elsevier; 2009, p 76.)

As a key mediator of the stress response, cortisol facilitates lean muscle catabolism to provide substrate for hepatic gluconeogenesis, synthesis of acute phase reactants, and expansion of the immune system. Hypercortisolemia represents a key mediator in hyperglycemia of critical illness discussed later.[49] Both protein catabolism and hyperglycemia, if prolonged in the ICU, can become maladaptive and associated with increased risk for adverse outcomes including death (see also Chapter 81).

Hemodynamics[50-52]

Cortisol's permissive effects on maintaining a normal hemodynamic status includes augmenting cardiac contractility, maintaining vascular tone, promoting endothelial integrity, upregulating vasoactive receptors, and increasing catecholamine synthesis.

Assessing the Cortisol Stress Response

Historically, adrenal function during critical illness has been quantified by random total plasma cortisol concentrations or by calculating the difference between a corticotropin-stimulated plasma cortisol concentration minus a baseline cortisol concentration. In the latter case a so-called delta value less than 9 μg/dL was previously considered evidence of adrenal insufficiency (AI) or inadequate adrenal reserve.[53] Depending on the cutoff value chosen (10, 15, 18, 20, 25 μg/dL), critically ill patients may demonstrate a wide range of adrenal insufficiency occurrence when random baseline total plasma cortisol concentrations are evaluated.[54]

Examples of cortisol testing approaches are illustrated in Table 85e.1.

A detailed evaluation of critically ill adults with sepsis indicated that those patients with a high baseline plasma cortisol concentration but delta cortisol concentration less than 9 μg/dL exhibited the highest risk for hemodynamic instability and mortality.[55] In fact, a subsequent interventional trial of adjunctive

hydrocortisone for adult septic shock was designed on the basis of these findings.[56] However, a confirmatory trial failed to replicate this finding and concluded that corticotropin stimulation testing provided no information regarding which patients with septic shock would benefit from hydrocortisone replacement therapy.[57] Although the overnight metyrapone test is not generally applicable to critically ill patients, it has been employed as a gold standard in an attempt to identify an adult population with an apparent inadequate adrenal response to the stress of critical illness. Metyrapone administration will result in increased ACTH and the cortisol precursor 11β-deoxycortisol. Among adult patients with severe sepsis, approximately 60% exhibited an abnormal cortisol stress response per the overnight metyrapone test. The best predictors of this scenario included a baseline total cortisol of less than or equal to 10 μg/dL, a delta total cortisol of less than or equal to 9 μg/dL, or a free cortisol less than 2 μg/dL.[53]

Serial low-dose corticotropin stimulation testing in addition to comprehensive ACTH, dehydroepiandrosterone, and cytokine measurements in a cohort of critically ill Turkish children revealed that 28% exhibited AI that was largely resolved by 2 weeks.[58] Baseline cortisol levels of the patients were significantly higher than those of healthy children. Patients with multiple organ dysfunction syndrome (MODS) had significantly higher concentrations of baseline and stimulated cortisol, as well as higher procalcitonin, TNF-α, and IL-6 concentrations compared with those without MODS. Cortisol, ACTH, and dehydroepiandrosterone concentrations were higher among the children with AI compared with those without AI. Interestingly, sepsis as an antecedent of critical illness was not associated with an increased risk of AI. Similarly, among 381 critically ill Canadian children also evaluated by low-dose corticotropin stimulation testing, AI was noted in 30.2%.[59] Children with AI exhibited higher baseline cortisol concentrations, were significantly older, and demonstrated an increased need for volume resuscitation and vasoactive-inotropic support.

Free Cortisol

Although most cortisol is bound to transcortin or serum albumin, the free fraction comprising 10% to 15% of the total is actually responsible for the protean effects of cortisol. Accordingly, it has been suggested that perhaps free cortisol rather than total cortisol concentrations might be more reliable in terms of identifying a population that would most benefit from cortisol replacement therapy.[60] For most critically ill patients, cortisol-binding globulin is typically decreased and the percent of cortisol as the free fraction increased. Moreover, with corticotropin adrenal stimulation, free cortisol increases substantially more than total cortisol.[61-63] Assessing total cortisol concentrations may be especially problematic in critically ill patients with low albumin.[60] Multiple limitations of corticotropin stimulation testing to assess total cortisol during critical illness have been summarized.[64] Free cortisol may be assessed in urine and saliva,[65] but blood contamination of either specimen may limit this approach. Free cortisol concentrations may be determined among critically ill children using microdialysis or centrifugal ultrafiltration plasma fractionation.[63] In an investigation that measured both total and free cortisol concentrations in a general population of critically ill children, the majority exhibited both total and free cortisol concentrations that would be considered inadequate by

the metyrapone testing criteria mentioned earlier. However, none of these children demonstrated evidence of corticosteroid insufficiency (hypotension, hyponatremia, hypoglycemia).[19] These results question the use of current thresholds for assigning diagnoses of AI or critical illness–related corticosteroid insufficiency in critically ill children and further suggest that clinicians currently are unable to reliably define adequacy of the adrenal response to the stress of critical illness.

Adrenal Insufficiency in the Intensive Care Unit

Adrenal insufficiency may be classified under two major categories: primary, in which direct malformation or destruction of the adrenal glands occurs, and secondary, in which there is typically loss of HPA axis integrity. The latter situation is most often encountered among critically ill patients.

Primary Adrenal Insufficiency

Primary adrenal insufficiency or Addison disease is typically encountered in adult patients and is included in a group of disorders termed *autoimmune adrenalitis*.[66,67] Signs and symptoms of Addisonian crisis include intercurrent illness with a history of chronic weight loss and anorexia, dizziness, lethargy, and chronic pigmentation. Symptoms more likely to be associated with admission to the ICU include sudden hypovolemic shock, hyperkalemia, vomiting, diarrhea, abdominal pain, and coma. Other causes of primary adrenal failure include congenital adrenal hyperplasia, an autosomal recessive disorder, with approximately 90% of cases secondary to 21 hydroxylase deficiency (CYP21A2 mutation).[68,69] The next most common congenital inborn error of metabolism is 11-hydroxylase deficiency.[70] Primary congenital adrenal failure can also occur among infants with adrenoleukodystrophy associated with a metabolic defect in metabolism of very-long-chain fatty acids. Other causes of congenital adrenal failure include Wollman disease and familial unresponsiveness to ACTH involving altered *MC2R* as previously discussed.[71]

Because of its precarious circulation associated with a subcapsular arteriolar plexus, the adrenal glands are subject to hemorrhage and infarction, particularly in the setting of septic shock. Such events, termed the *Waterhouse-Friderichsen syndrome,* were initially described as adrenal apoplexy.[72,73]

Although a variety of drugs inhibit the sequential steps in cortisol synthesis, etomidate is particularly notable, as it is increasingly being used as a sedative to facilitate endotracheal intubation without adversely affecting hemodynamics. However, in an observational cohort study of 60 children with meningococcal severe sepsis, it was noted that a single bolus of etomidate was associated with impaired adrenal function, specifically 11β–hydroxylase activity.[74] A meta-analysis of seven studies concluded that administration of etomidate for endotracheal intubation was associated with higher rates of adrenal insufficiency and mortality among patients with sepsis.[75]

Secondary Adrenal Insufficiency

Secondary adrenal insufficiency in the pediatric ICU (PICU) can be seen with pituitary disorders (eg, among children following surgical resection of a

craniopharyngioma).[76] In addition, long-term corticosteroid administration among patients with recalcitrant asthma, patients with oncologic or rheumatologic diagnoses, or transplantation patients results in suppression of ACTH release, occasionally with resultant adrenal atrophy.[77,78]

Probably the most controversial cause of secondary adrenal failure seen in the ICU is so-called relative adrenal insufficiency or critical illness–related corticosteroid insufficiency (CIRCI).[79] A seemingly inadequate adrenal response relative to the magnitude of stress characterizes CIRCI. This situation is a dynamic, typically reversible state that is thought to be secondary to both decreased cortisol production and tissue resistance to cortisol, as discussed previously. Multiple pediatric observational studies, most associated with sepsis, have examined associations with random, baseline serum cortisol concentrations with various outcomes.[74,80-83] These studies ascertain cortisol circadian rhythm among children with sepsis. As sepsis severity increased (eg, sepsis → septic shock → sepsis death), proinflammatory mediator concentrations (eg, IL-6, TNF-α) and ACTH increased, while cortisol concentrations decreased. Both serum cortisol and ACTH concentrations correlated with illness severity per PRISM, organ dysfunction scores, lactate, and C-reactive protein. Pediatric observational studies have also examined corticotropin stimulation testing among children with severe sepsis.[84-88] These studies in general demonstrated that, like adults, low delta cortisol is common among children with sepsis. Among children with a low delta cortisol, illness severity is higher, as is requirement for vasoactive-inotropic resuscitation. Such children also more frequently demonstrate vasoactive-inotropic resistance shock and multiple organ dysfunction syndrome. Chronic illness and the degree of organ dysfunction at presentation, as well as low delta cortisol concentration, predicted risk of mortality.

Corticosteroid Side Effects

Corticosteroid therapy has been associated with increased risk for hospital-acquired infection among a general population of critically ill children[89] and in children following surgery for congenital heart disease.[90] In the latter investigation, children who received hydrocortisone were nearly 30 times more likely to develop a central catheter–associated infection as compared with children who did not receive hydrocortisone. With increasing recognition of the key role of immunosuppression in the pathogenesis of sepsis, it is noteworthy that children with sepsis demonstrate widespread repression of gene programs associated with adaptive immunity and that this gene repression is further enhanced with concurrent corticosteroid administration.[39] Loss of HLA-DR (the antigen presentation protein motif) on monocytes appears to be an early event in sepsis, and persistence of HLA-DR downregulation is associated with sepsis severity and sepsis prognosis. Endogenous cortisol mediates transcriptional regulation of this process; the role of exogenous corticosteroids in this setting has not been detailed.[91]

Dissolution of lean body mass mediated by both endogenous and exogenous[45] corticosteroids represents a key element of the stress response.[47] Although this may be beneficial in the short term, prolonged corticosteroid mediated muscle catabolism can be associated with ICU weakness (including the diaphragm) and hyperglycemia. Muscle weakness has been associated with prolonged mechanical ventilation weaning.[48,92-94] Hyperglycemia has been associated with a variety of adverse events

in the PICU as detailed later.[49] Additional important clinical consequences of protein catabolism that may be exaggerated by exogenous corticosteroid administration include impaired wound healing, hypoalbuminemia, disordered coagulation, and impaired gut function with bacterial translocation.[95]

In the CORTICUS sepsis interventional trial,[57] transient hypernatremia was also noted among patients receiving hydrocortisone. Although gastrointestinal hemorrhage represented an important side effect in previous clinical trials examining the potential utility of high-dose methylprednisolone as adjunctive therapy in sepsis, this side effect has not been problematic in later investigations using low-dose hydrocortisone. Among adult critically ill patients with acute lung injury, corticosteroid administration is associated with transition to delirium.[96]

Long-term exposure to corticosteroids results in characteristic side effects (eg, as manifested in children with bronchopulmonary dysplasia).[97] In the absence of obvious exogenous steroid administration, true Cushing's syndrome is diagnosed as a high 24-hour urine-free cortisol concentration that is not suppressed by administration of dexamethasone.[98] Clinical characteristics of Cushing syndrome include hypertension, hypokalemic alkalosis, proximal myopathy, hyperglycemia, osteoporosis, opportunistic infections, psychiatric problems, and central obesity with characteristic striae.

Alterations of Glucose Homeostasis

Glucose Homeostasis in Health

Under normal conditions, glucose concentration is tightly regulated by the neuroendocrine system. Control of blood glucose is complex, involving interaction among liver, pancreas, muscle, adipose tissue, pituitary, adrenals, and bone. The brain and periphery conduct a constant biochemical conversation by which the periphery informs the brain about its metabolic needs and the brain addresses these needs through its control of somatomotor, autonomic, and neurohumoral pathways involved in energy intake, expenditure, and storage.[99,100]

Glucose is obtained from three sources: intestinal absorption of food, glycogenolysis, and gluconeogenesis. Once transported into cells, glucose can be stored as glycogen or it can undergo glycolysis to pyruvate. Pyruvate can be reduced to lactate, transaminated to form alanine, or converted to acetyl coenzyme A (CoA) (see also Chapter 80). Acetyl CoA can be oxidized in the mitochondrial tricarboxylic acid cycle to carbon dioxide and water, converted to fatty acids for storage as triglyceride, or serve as substrate for ketone body or cholesterol synthesis. Although glycogenolysis can occur in most tissues in the body, only liver and kidneys express the enzyme glucose-6-phosphatase, which is required for release of cellular glucose into the bloodstream. The liver and kidneys also contain the enzymes required for gluconeogenesis. Of the two organs, the liver is responsible for the bulk of glucose output; the kidney supplies only 10% to 20% of glucose production during fasting.

Current understanding of glucose homeostasis is centered on glucose-induced secretion of insulin from pancreatic beta cells and insulin effect on glucose metabolism in peripheral tissues. The switch from glycogen synthesis during and immediately after meals to glycogen breakdown and gluconeogenesis is orchestrated by hormones of which insulin is centrally important. Plasma insulin concentrations

increase to peak levels of 50 to 100 μU/mL after meals. This surge in insulin activates glycogen synthesis, enhances peripheral glucose uptake, and inhibits glucose production. In addition, lipogenesis is stimulated while lipolysis and ketogenesis are suppressed. During fasting, plasma insulin level falls to less than or equal to 5 to 10 μU/mL. Hormones including glucagon, catecholamines, cortisol, and growth hormone (GH) counteract the effects of insulin and promote glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis.

Insulin binds to its receptor, a tyrosine kinase expressed in many cell types. It then triggers a complex series of events that lead to insulin receptor substrate binding, recognition of the activated insulin receptor substrate by intracellular signal transducing proteins, and activation of postreceptor signaling pathways. This action activates phosphatidylinositol-3 kinase and nuclear gene expression modulating proteins. These in turn stimulate glycogen synthesis and inhibit glycogenolysis in liver and muscle, increase glucose uptake by increasing glucose transporter (GLUT)-4 on the cellular membrane, downregulate the expression of phosphoenolpyruvate carboxykinase (PEPCK), and inhibit fructose 1,6-bisphosphatase, the key rate-limiting steps of hepatic gluconeogenesis. Response to insulin is tissue specific (see Fig. 85.5).

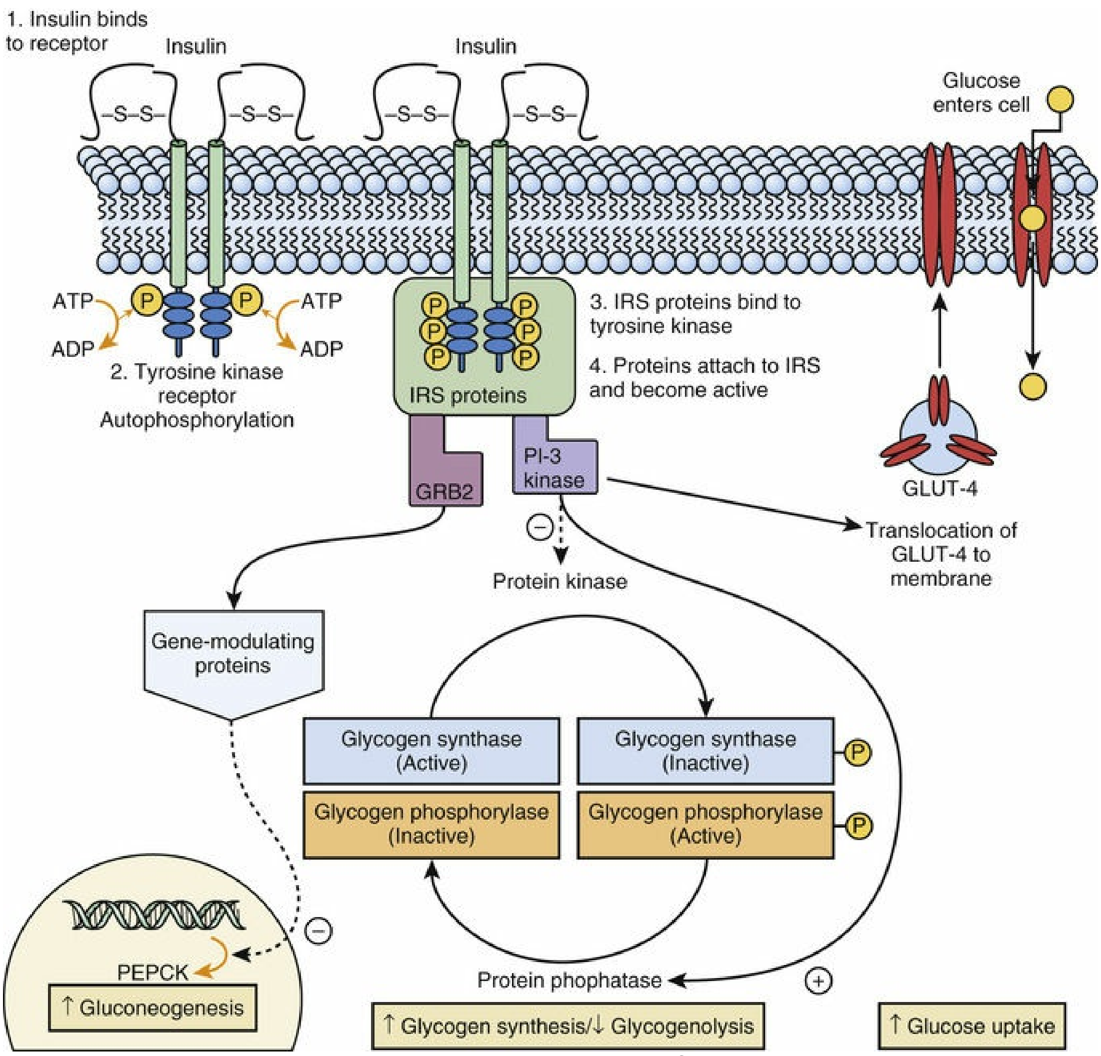

FIG. 85.5 Insulin receptor signaling pathways. After insulin attaches to the

receptor, it activates tyrosine kinase activity, causing the enzyme to autophosphorylate. Insulin receptor substrate (IRS) proteins bind to the now active tyrosine kinase receptor. IRS then serves as a loading dock for several different proteins. Growth factor receptor–bound protein 2 (GRB2) is one of the proteins involved in signal transduction and will activate gene-modulating proteins that inhibit phosphoenolpyruvate carboxykinase (PEPCK) expression in the nucleus, thereby decreasing gluconeogenesis. PI-3 kinase also becomes active after attaching to IRS, and this leads to inhibition of protein kinases and stimulation of protein phosphatases. This results in increased glycogen synthesis and decreased glycogenolysis. Activated PI-3 kinase also results in translocation of glucose transporter 4 (GLUT-4) to the membrane, facilitating glucose uptake.

Recent findings support the concept of even more complex mechanisms for glucose homeostasis. These include the "gut-brain-liver" axis, hepatic independent glucose sensing, and a bone-pancreas loop. Brain neurons are equipped with mechanisms allowing them to detect and respond to changes in circulating levels of several hormones and metabolites. Following ingestion of food, presence of nutrients in the gastrointestinal tract initiates complex neuronal and hormonal responses, informing the brain of ongoing change in nutritional status. The gut is richly supplied with both sympathetic and parasympathetic afferent fibers of the autonomous nervous system. Metabolic sensing neurons (previously called "glucosensing") respond to glucose, fatty acids, and metabolites from the periphery. These neurons use glucose and other metabolites as signaling molecules to regulate their membrane potential and neuron signaling. In glucose-excited neurons, the increase in extracellular glucose leads to augmentation of the ATP-to-ADP ratio and closure of the K_{ATP} channels, which leads to plasma membrane depolarization and Ca^{2+} entry through voltage-gated channels, thereby increasing neuronal activity and neurotransmitter secretion.

The gut also informs the brain of these changes by secreting a host of gut peptides including ghrelin, cholecystokinin (CCK), and glucagon-like peptide-1 (GLP-1).[101] Signals from the gut are integrated by the hindbrain and projected to the hypothalamus.[102] The brain can then signal peripheral tissues to alter their glucose uptake and/or secretion appropriately, by both insulin-dependent and independent mechanisms. A functional network of enzymes and transcription factors enables independent glucose sensing in the liver, which is also an essential component of systemic glucose and energy homeostasis.[103]

Recently, bone has emerged as another endocrine "gland." Osteocalcin, a bone-specific protein, was identified as a hormone that stimulates insulin sensitivity in peripheral tissues (liver, muscle, and adipose tissue) and insulin secretion by the pancreas. The latter is accomplished by direct effect on beta cells and indirectly by promoting gut secretion of GLP-1.[104]

In the current era, obesity is an increasingly prevalent disease in the pediatric population. Glucose metabolism in patients with obesity is altered in health with chronic inflammation and dysregulated immune pathways, leading toward impaired glucose metabolism.[105]

Current understanding of the impact of obesity on children during critical illness is limited. This subset of patients may require special attention when dealing with stress hyperglycemia.

Glucose Metabolism

Sugars are essential for cellular function. They serve five main purposes: source of energy (utilization and storage), source of carbon skeletons, osmolality activity, signaling, and transport function. Glucose is a polar molecule, and its transport into cells occurs largely by active transport or facilitated diffusion.

The human genome codes for more than 20 sugar transporters (7 sodium-glucose symporters [SGLTs], 14 glucose transporters [GLUTs], 1 NaGLT1, and 1 SWEET).[106] Of the 14 members of the GLUT family, 13 are facilitative transporters. One or more GLUT proteins are expressed in virtually every cell type of the human body. Within the GLUT family members, 11 of 14 are capable of transporting glucose, although it is highly likely that the principal physiologic substrates for some of these proteins have not been identified. GLUT-1 to GLUT-4 facilitate the glucose uptake in myriad of cell types and are well summarized in Table 85.2. The redundancy of proteins transporting glucose can be easily explained by the critical nature of this sugar as circulating fuel in humans and the consequent need for multiple glucose transporters with different kinetics and regulatory properties that are expressed in a cell-type specific fashion.[107] Transporter activity can be efficiently controlled through transporter delivery or endocytosis, as best exemplified in the case of GLUT-4 trafficking by insulin.

TABLE 85.2

Characteristics of Glucose Transporters

GLUT-1 and GLUT-3 are responsible for maintaining basal rate of glucose uptake. Their high glucose affinity facilitates constant uptake from the bloodstream. GLUT-2 has low affinity, which allows glucose sensing and glucose entry proportional to blood levels (glucose enters only when blood levels are high). Because the bulk of blood glucose is taken up by skeletal muscle in the presence of elevated insulin and GLUT-4 transport activity is rate limiting for this process, GLUT-4 plays a critical role in the regulation of whole-body glucose homeostasis.

GLUT Receptor	Distribution	Glucose Affinity	Significant Glucose Uptake	Insulin Dependence	Additional Remarks
GLUT-1 (55-kDa, 45-kDa isoforms)	All human tissues, often in conjunction with ≥1 additional GLUT isoforms	High	Basal glucose uptake	Insulin independent	Highly expressed in brain endothelial cells. Different isoform expressed in astrocytes, choroid plexus, and ependymal cells. Common in erythrocytes
GLUT-2	Beta cells, liver, renal tubules, small intestine, some CNS cells	Low	Postprandial glucose uptake	Insulin independent	Major basolateral glucose transporter isoform in intestine. Absolutely required for renal glucose reabsorption in kidney. Associated with glucose-sensing mechanisms in brain (mostly in the hypothalamus)
GLUT-3	All human tissues. Widely expressed in parenchymal neurons, placenta and leukocytes	High	Basal glucose uptake	Insulin independent	Major transporter in CNS neurons
GLUT-4	Skeletal muscles, myocardium, adipocytes		Glucose uptake typically postprandial transporter expression is insulin dependent	Insulin dependent, translocation from cytosol to cell membrane	
GLUT-5	Brush border of intestinal cells, liver, spermatozoa	N/A		Primarily transports fructose	

CNS, central nervous system; *GLUT*, glucose transporter.

Hyperglycemia

Hyperglycemia has been defined by the World Health Organization as blood glucose levels greater than 126 mg/dL when fasting. There are no specific age-adjusted levels for infants and children. No guidelines specifically define stress hyperglycemia, although a common definition describes it as transient hyperglycemia resolving spontaneously after dissipation of acute severe illness. Stress hyperglycemia (SHG) was first described by Thomas Willis in the 17th century. Initially identified as an appropriate adaptive harmless or even beneficial short-term physiologic response to critical illness, it is now considered a risk factor, especially because advanced critical care has improved survival and extended ICU length of stay (LOS).[108]
Hyperglycemia is common in nondiabetic, critically ill children and occurs in up to 86% of patients.[109]

Stress Hyperglycemia and Outcomes

Studies in children have challenged the assertion that hyperglycemia is beneficial or inconsequential, by observing that SHG is associated with worse clinical outcomes. A retrospective study from a single PICU examined 1173 admissions. Hyperglycemia was prevalent and associated with increased morbidity as characterized by increased LOS and mortality.[110] Association between hyperglycemia and worse outcome in children was also demonstrated in specific disease processes such as traumatic brain injury,[111] general trauma,[112] severe burns,[113] septic shock,[114] meningococcal sepsis,[115] and postoperative congenital heart disease.[116,117] Hyperglycemia is common in infants with necrotizing enterocolitis admitted to the NICU and is associated with increased late mortality and NICU LOS.[118] SHG is also associated with specific complications such as increased risk of venous thromboembolism in nondiabetic children[119] and more frequent nosocomial infections including surgical site infection.[120]

While clearly prevalent in critically ill children, some studies were unable to show clear association between hyperglycemia and worse outcomes. One retrospective study found that hyperglycemia within 24 hours of PICU admission was associated with increased rate of mechanical ventilation, ICU LOS, and mortality, but when controlled for disease severity, it was not independently associated with increased morbidity or mortality.[121] Another retrospective study evaluated the association between blood glucose level and duration of mechanical ventilation and ICU LOS in mechanically ventilated patients with bronchiolitis. Hyperglycemia was a frequent event in this patient population, yet results failed to show independent association with worse outcomes.[122] Such studies support the notion that hyperglycemia may be a marker of severity of illness rather than a cause.

Preexisting nutritional status may also impact outcomes associated with hyperglycemia in the critically ill child. A prospective study from Brazil reported that compared with those well nourished, malnourished patients with hyperglycemia were at greater risk of mortality independent of severity of illness.[123] Obesity is prevalent among critically ill pediatric patients, but the available literature on the relationship between obesity and clinical outcome is limited.[124] There exist no available studies examining the relationships between obesity and SHG.

With current knowledge, it is clear that hyperglycemia is prevalent in critically ill

children and is associated with worse outcome in some disease processes but not in others. Many studies are not controlled for severity of illness, making it difficult to interpret results. Different definitions for SHG used by different authors (range of 126–250 mg/dL, in 9 key pediatric studies of association of SHG and mortality)[125] make it even harder to compare results and create thresholds for treatment. Moreover, thus far, all studies have failed to establish cause-and-effect relationships, yet many suggest that aggressive maneuvers should be used to normalize plasma glucose levels. Younger patients (<1 year) are at higher risk for spontaneous hypoglycemia and require special consideration when treating hyperglycemia with insulin.[126]

Pathophysiology of Stress Hyperglycemia

During stress the normal mechanisms that counteract hyperglycemia are overwhelmed, causing a persistent unchecked state of high glucose blood levels. These changes help the body provide glucose to meet increased metabolic demands. SHG results from increased levels of counter regulatory hormones (epinephrine and norepinephrine, glucagon, cortisol, and growth hormone) and proinflammatory cytokines (TNF-α, IL-1, and IL-6) (see also Chapter 81). The overall effect is increased hepatic and renal glucose production. Peripheral and hepatic insulin resistance is a well-recognized phenomenon in critically ill patients. It is characterized by organ-specific alteration in glucose utilization/production and impaired insulin mediated uptake.[108] Insulin concentrations may be elevated or decreased. Use of carbohydrate-based feeds, glucose-containing fluids, and drugs like epinephrine and corticosteroids may exacerbate the picture.

High hepatic output of glucose, especially through gluconeogenesis, is the most important contributor to SHG. Glycogen stores are limited and rapidly depleted during stress. Lactate, pyruvate, and alanine are the main precursors used by the liver for gluconeogenesis. Often overlooked, renal-derived gluconeogenesis is a significant contributor (up to 40%) of glucose production during stress, mostly in response to epinephrine.[127] The principal precursors for renal gluconeogenesis are lactate and glycerol (see Fig. 85.6).

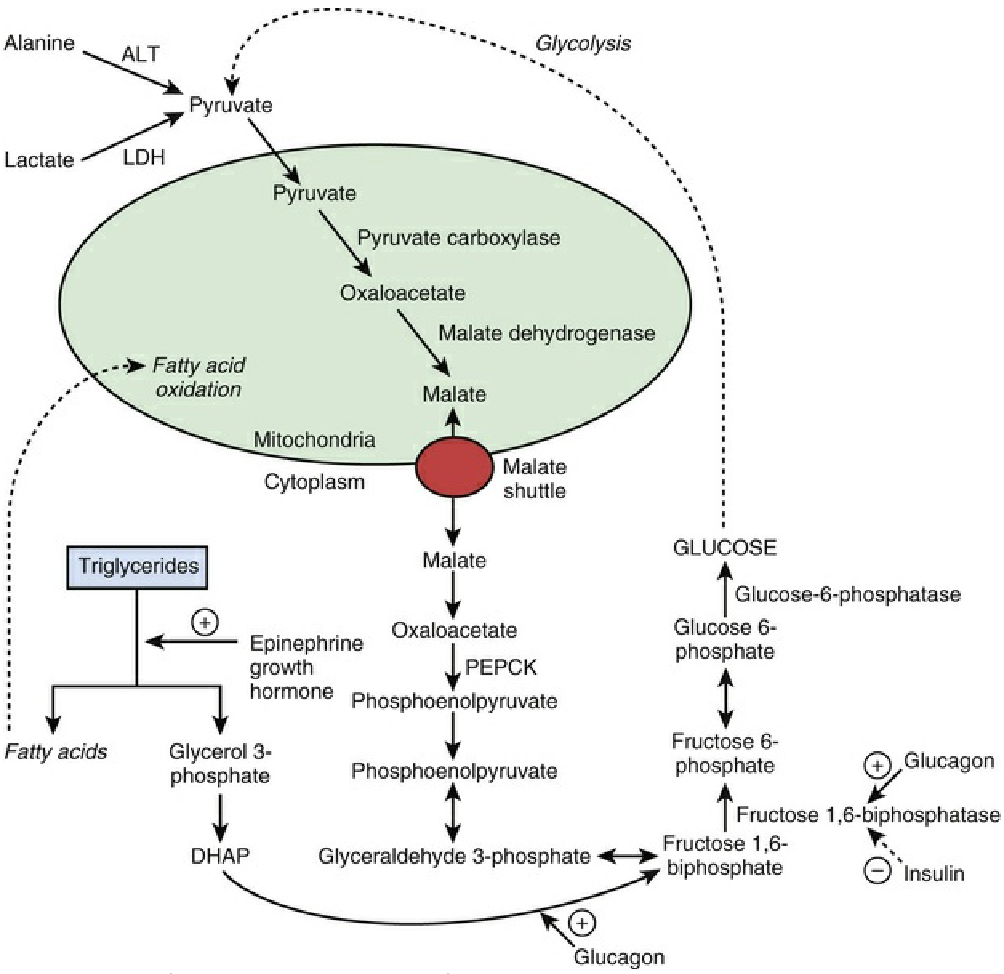

FIG. 85.6 Schematic overview of gluconeogenesis. Pyruvate is generated from glycolysis, lactate, or alanine through pyruvate kinase, lactate dehydrogenase (LDH), and alanine-amino transferase (ALT), respectively. Pyruvate enters the mitochondria freely and is converted into oxaloacetate, which is then converted into malate in order to enter the malate shuttle and cross the mitochondrial membrane into the cytoplasm, where it is again converted into oxaloacetate and through phosphoenolpyruvate carboxykinase (PEPCK) is converted into phosphoenolpyruvate that serves as substrate for a series of enzymatic-driven reactions and is finally converted into glucose. It should be noted that the rate-limiting step of gluconeogenesis is the conversion of fructose biphosphate into fructose 6-phosphate and is regulated by the actions of glucagon (stimulates) and insulin (inhibits) on fructose 1,6-biphosphatase. Triglycerides also contribute to gluconeogenesis by their breakdown into fatty acids and glycerol 3-phosphate. The latter is then transformed into dihydroacetone phosphate and then into fructose 1,6-biphosphate to follow the rest of the gluconeogenic pathway and result in the generation of glucose.

Mechanisms underlying insulin resistance occur at several levels. Insulin receptor levels are unchanged in most short-term animal models of sepsis. However, reduction in insulin receptors is seen in longer-term models.[128] Although the level of insulin receptor may be unchanged, TNF-α activates protein kinase B, inducing serine phosphorylation of insulin receptor substrate 1, and inhibits insulin receptor tyrosine kinase, thereby reducing cellular utilization of glucose through GLUT-4.

TNF-α, hypoxia, and insulin-like growth factor binding protein 3 (IGFBP-3) inhibit peroxisome proliferator activator (PPARγ), which impacts gene expression including adiponectin, a hormone capable of sensitizing cells to insulin effect. Inhibition of PPARγ has significant impact on cell metabolism in sepsis and other stress conditions, including insulin resistance during SHG.

A different mechanism for hepatic insulin resistance is associated with increase in growth hormone (GH) and reduction in insulin growth factor–1 (IGF-1). Effects of IGF-1 are similar to insulin in terms of cell growth promotion. During critical illness, GH levels increase significantly, but there is a fall in hepatic GH receptor with disruption of downstream signaling. IGF-1 levels drop in response to proinflammatory cytokines, especially TNF-α with decreased IGF-1 synthesis. In addition, low IGF-1 may result from upregulation and increased affinity of its binding protein IGFBP-3, reducing the free active protein.[129]

Elevated insulin levels are common in adults. The critically ill child may present with insulin deficiency due to beta cell dysfunction and impaired insulin production (direct effect of proinflammatory cytokines), which contributes to stress hyperglycemia.[130,131]

Despite insulin resistance, critical illness is associated with increased glucose utilization, mostly through the insulin-independent transporter, GLUT-1. Additionally, impaired nonoxidative glucose disposal results from reduced skeletal muscle glycogen synthesis.

Insulin resistance ultimately promotes a catabolic state in which lipolysis is activated. Lipotoxicity, glucotoxicity, and inflammation are key components of global SHG.

Hyperglycemia itself further exacerbates the inflammatory and oxidative stress response and proinflammatory cytokine storming, promoting a vicious cycle whereby SHG leads to further SHG.

During critical illness, specific interventions can mediate development of SHG. Use of vasoactive-inotropic drugs such as epinephrine, norepinephrine, and dopamine is frequently associated with SHG. Epinephrine stimulates β_2 receptors, promoting glycogenolysis and gluconeogenesis, and increases insulin resistance by release of glucagon and cortisol. It also reduces insulin secretion via stimulation of α_2 receptors. Effects of dopamine and norepinephrine are less prominent due to lesser activity at the β_2 receptors. Several medications commonly used in the ICU setting may result in development of SHG (eg, patients frequently receive antifungal and antibiotic medications in large volumes of dextrose-containing fluids). Corticosteroids can increase the risk of SHG, especially when given in bolus doses. Thiazide diuretics are also associated with the occurrence of SHG. Calcineurin inhibitors such as tacrolimus and cyclosporine can result in SHG and post-transplant diabetes due to decreased insulin biosynthesis and release.

Nutritional support practices strongly influence SHG (see also Chapter 87). Critically ill children are frequently prescribed parenteral nutrition (PN). Provision of excess carbohydrate calories in PN can result in SHG. Overfeeding is common in critically ill children, regardless of whether PN or enteral nutrition is employed. Studies have shown that commonly used predictive equations to calculate caloric needs are inferior to targeted indirect calorimetry and frequently result in overprescription of calories.[132]

Mechanisms of Stress Hyperglycemia Adverse Outcomes

Postulated mechanisms by which SHG cause harm include direct cellular damage and alterations of essential organ function. In diabetic patients, four main molecular mechanisms have been identified in glucose-mediated complications: (1) increased polyol pathway flux; (2) increased advanced glycation end product formation; (3) activation of protein kinase C isoforms; and (4) increased hexosamine pathway flux. Each of the four pathogenic mechanisms reflects a hyperglycemia-induced process, namely overproduction of superoxide anion by the mitochondrial electron-transport chain.[133] Diabetes-related injury develops over years, but some common mechanisms parallel acute stress-related hyperglycemia. During SHG, overexpression of insulin independent transporters (GLUT-1 to GLUT-3) results in glucose overload and toxicity essentially in every organ.[134] Cells damaged by hyperglycemia are primarily those unable to effectively control their intracellular glucose concentration, notably neuronal, capillary endothelium, and renal mesangial cells. Glucose overload results in excessive glycolysis and oxidative phosphorylation with increased production of reactive oxygen species such as superoxide anion, the same toxic end product involved in the injury pathway for diabetic patients. Reactive oxygen species cause mitochondrial dysfunction and altered metabolism with subsequent apoptosis and cellular and organ system failure in the critically ill child. Glucose overload can also lead to glycation, the reaction of glucose with the amine group of proteins, which may impair the function of these proteins.

Hyperglycemia is a risk factor for infection in acute illness.[108] The relative bacterial overgrowth witnessed in hyperglycemia may be partly due to altered host defenses. Acute, short-term hyperglycemia impairs macrophage activity, reduces polymorphonuclear leukocyte chemotaxis and bactericidal capacity, and alters complement fixation in critically ill patients.[135] SHG affects all major components of innate immunity and impairs the ability of the host to combat infection.[135] Furthermore, hyperglycemia is associated with poor gut motility, a factor that may be important in bacterial overgrowth and translocation. A raised blood glucose level is also recognized as being proinflammatory and pro-oxidant. Mononuclear cells isolated from healthy volunteers exhibited higher levels of NF-κB binding activity, raised reactive oxygen species, and increased levels of TNF-α mRNA following exposure to hyperglycemia.[136]

Hyperglycemia also results in a hypercoagulable state partly through the increased expression of tissue factor, which is both procoagulant and proinflammatory.[137] SHG is implicated in other abnormalities such as endothelial dysfunction and alteration in vascular smooth muscle tone, commonly observed during critical illness.[138] Likewise, hyperglycemia has been associated with deleterious effects on the nervous system. Underlying mechanisms in critical illness remain largely speculative and are often extrapolated from knowledge in diabetic patients. Hyperglycemia-induced blood-brain barrier permeability, oxidative stress, and microglia activation may play a role and compromise neurons and glial cell integrity.[139]

Clinical Trials Examining Management of Critical Illness

Hyperglycemia

In 2001, a single-center adult study reported reduction of hospital mortality by more than 30% using a tight glycemic control (TGC) protocol.[140] The effect was attributed to the actual glycemic control rather than the infused insulin dose. These impressive results brought the issue of SHG into clinical attention and fostered considerable discussion. Previously seen as an aspect of a normal stress response, physicians now started viewing SHG differently, considering it as a major cause or contributor to pathophysiology that must be aggressively addressed and treated. The appeal of such straightforward intervention was too great to resist.[141] Subsequent studies failed to reproduce these results, yet guidelines generated by professional societies warmly recommended tight glycemic control for adult critically ill patients.[142,143] A large international randomized multicenter study involving more than 6000 adult patients[144] and many other smaller studies reported that tight glycemic control increased mortality and risk for severe hypoglycemia among adults in the ICU. With such consistent negative results, it was difficult to continue and support tight glycemic control for all ICU adult patients. Guidelines were revised and currently recommend using a higher glucose threshold for initiation of insulin therapy, avoiding specific range for glycemic control, and focusing on good monitoring and safety margins to avoid hypoglycemia and glucose variability.[145] While tight glycemic control became standard of care for adults, the pediatric critical care community was hesitant to adopt any guidelines or consistent standard approach.[146] There are only a handful of pediatric studies related to glycemic control and outcome.

A multicenter trial of insulin with continuous 20% dextrose infusion in very-low-birth-weight neonates was terminated prematurely for concerns of futility and potential harm associated with hypoglycemia.[147] This study took a proactive approach toward glycemic control in that the treatment group received insulin with glucose infusion regardless of their blood glucose level before the intervention. Considering the study population and the fact that the study was not designed to treat hyperglycemia, it is difficult to compare the results with any other pediatric study.

Following early adult data and subsequent recommendations for TGC, few PICUs implemented TGC protocols. However, two retrospective studies reported the impact of this intervention. One retrospective study from a single center reported lower infection rates and improved survival among children with severe burns, following initiation of a TGC protocol when compared with historic controls.[148] A second retrospective study from two centers compared all nondiabetic PICU patients who presented with hyperglycemia of greater than 150 mg/dL and treated with insulin with historic controls who were not treated with insulin. The authors concluded that blood glucose control with insulin appeared to be associated with worse outcome.[149]

Four randomized prospective studies have examined the association between TGC and clinical outcomes. The first study published in 2009, derived from a single center in Belgium, enrolled a mixed medical/surgical patient population, although 75% of the subjects had undergone cardiac surgery.[150] The study targeted age-adjusted glycemic range for infants and children. Results showed improved short-term outcome including mortality in the TGC group, despite the fact that the TGC group

had an unacceptable rate (25%) of severe hypoglycemia (<40 mg/dL). The concern for impact of hypoglycemia on neurodevelopment cognitive long-term outcome was addressed by the same group with 4-year neurocognitive follow-up that ascertained that brief hypoglycemia evoked by TGC was not associated with worse neurocognitive outcome.[151] Three subsequent subgroup analyses were conducted using the parent investigation[150] database. The first examined the effects of the TGC protocol on the somatotropic axis and reported that intensive insulin therapy did not reverse the catabolic state of critical illness.[152] The second, focused on the thyroid axis, concluded that TGC further accentuated the peripheral inactivation of thyroid hormone.[153] In addition, a predefined small subgroup analysis (14 neonates) found that TGC in neonates undergoing cardiac surgery appeared to protect the myocardium and reduce inflammation.[154]

In 2010, a single-center study focusing on pediatric patients with severe burns concluded that intensive insulin therapy significantly decreased infections and sepsis and improved organ function by decreasing inflammation.[155] A two-center prospective randomized trial published in 2012 enrolled 980 children who underwent surgery with cardiopulmonary bypass. The authors reported that TGC can be achieved with a low hypoglycemia rate; however, the study found no clinical benefit for TGC in terms of infection rate, mortality, LOS, or measures of organ failure when compared with standard care.[156] A post hoc analysis of this study demonstrated that TGC may, in fact, lower the rate of infection in children older than 60 days of age at the time of cardiac surgery when compared with standard care.[157] In a secondary analysis of this trial, insulin appeared to have no discernible impact on skeletal muscle degradation.[158] In 2014, a large multicenter randomized trial involving 13 centers in England reported that TGC in critically ill children had no significant effect on major clinical outcomes (number of days alive and free from mechanical ventilation at 30 days after enrollment), but patients in the TGC arm had lower need for renal replacement therapy and reduced total hospital stay and cost. These effects were mostly notable in the noncardiac patient population.[159]

A summary of prospective randomized pediatric studies of tight glycemic control with intense insulin therapy for stress hyperglycemia may be found in Table 85e.2.

TABLE 85e.2

Summary of Prospective Randomized Pediatric Studies of Tight Glycemic Control With Intense Insulin Therapy for Stress Hyperglycemia

Study	Leuven Study[150]	Burn Study[155]	SPECS Trial[156]	ChiP Trial[159]
ICU types; subjects; sample size Total subjects = n TGC = T Control = C	Mixed (75% cardiac surgery), single center. 317 infants <1 yr, 383 children, 1-16 yr. n = 700, T = 349, C = 351	Burn ICU, single center, children ≤18 yr with >30% TBSA burns. n = 239 T = 60, C = 179	Surgical cardiac ICU, 2 centers, infants 0-36 mo undergoing CPB. n = 980, T = 490, C = 490	Mixed, 13 centers in England. 60% cardiac surgery. 36-wk EGA to ≤16 yr, requiring at least 12 h of MV or VIS. n = 1389, T = 694, C = 675
TGC target range vs. standard care	50-80 mg/dL infants, 70-100 mg/dL children vs. 180-215 mg/dL	80-110 mg/dL vs. 140-180 mg/dL	80-110 mg/dL vs. no set target range for controls (provider discretion)	72-126 mg/dL vs. >216 mg/dL; insulin stopped when glucose <180 mg/dL
Primary outcome	Duration of PICU stay and markers of inflammation (CRP)	Effect on hypermetabolism and inflammation	Rate of health care–associated infections	Ventilator-free days truncated at 30 days
Secondary	Vital organ support,	Infection and	Mortality, length of stay, organ	Costs, complications,

outcomes	biochemical markers of MODS, secondary infection	sepsis, organ function, insulin resistance	failure, hypoglycemia	difference between cardiac and noncardiac patients
Mortality, TGC vs. control	2.6% vs. 5.7%, $P = 0.038$	4% vs. 11% $P = 0.14$	2% vs. 2%	5.1% vs. 5.0%
Secondary infections, TGC vs. control	29.2% vs. 36.8%	22.6% vs. 8.2% $P < 0.05$	5% vs. 5%	5.5% vs. 6.4%
Duration of ICU stay, TGC vs. control	3 vs. 3 (median days)	Not reported	3 vs. 3 (median days)	6.5 vs. 7.0 (mean days)
Severe hypoglycemia, <40 mg/dL, TGC vs. control	25% vs. 1% $P < 0.0001$	Not reported	3% vs. 1%	7.3% vs. 1.5%
Nutrition support	~60% of both groups, EN	Per treating physician	~40% of both groups, EN	Not reported
Main conclusion	Targeting of blood glucose concentrations to age-adjusted normal fasting concentrations improved short-term outcome of patients in PICU	Intensive insulin therapy improves postburn morbidity in children	TGC can be achieved with a low hypoglycemia rate after cardiac surgery in children. Does not significantly change any meaningful outcome compared with standard care	TGC had no significant effect on major clinical outcomes. Incidence of hypoglycemia was higher in the TGC group
Ancillary studies associated with the primary investigation	Effect of TGC on somatotropic axis[152] Effect of TGC on thyroid axis[153] Effects of TGC on myocardial injury and inflammation[154] Effect of TGC on long-term neurocognitive development[151]	None	Effect of TGC in lowering risk of infection[157] Effects of TGC on skeletal muscle catabolism[158]	Detailed clinical and economic evaluation of TGC[160]

CHiP, control of hyperglycemia in pediatric intensive care; *CRP*, C-reactive protein; *EGA*, estimated gestational age; *EN*, enteral nutrition; *MV*, mechanical ventilation; *PICU*, pediatric ICU; *SPECS*, Safe Pediatric Euglycemia after Cardiac Surgery trial; *TBSA*, total body surface area; *TGC*, tight glycemic control; *VIS*, vasoactive-inotropic support.

TGC with the use of intensive IV insulin therapy significantly reduced morbidity, mortality, or both in two randomized control trials involving children[150,155] but not in two others.[156,159] The patient population differed among the four studies with one involving children with severe burns, one involving children who were in the ICU following cardiac surgery, and two involving children who were in the ICU for a variety of reasons, although these studies included a significant portion of patients postcardiac surgery. The intervention increased the rate of severe hypoglycemia, although to a lesser extent in one study where continuous glucose monitoring was performed[156] and in another when nursing-directed glucose monitoring protocol was used.[159] These interventional trials are justified given that an association between pediatric hyperglycemia and mortality has been repeatedly reported.[109,116,161-164] Interestingly, hypoglycemia encountered in application of TGC was not associated with increased risk of neurocognitive disability in a 4-year follow-up study.[151]

Various reasons have been put forth to explain the observed differences in results in these studies. These include disparities in patient population and targeted age groups, difference in glucose control targets, variability in attaining these targets, differences in ICU-specific protocol, glucose control and glucose monitoring protocols, and different nutrition support practices. With current data, the pediatric critical care provider remains conflicted when treating a patient with hyperglycemia.

At this time the evidence for (or against) using TGC protocols with intensive insulin therapy to improve outcome (especially mortality) is inconclusive. Moreover, there is little knowledge about long-term outcomes. Large-scale multicenter studies, with strategies that combine continuous glucose monitoring with TGC, may yet afford the best chance to evaluate whether TGC using intensive insulin therapy in critically ill children is associated with improved outcome while limiting the risks associated with hypoglycemia.[165] There is also a need to identify patients who are at high risk for hyperglycemia-mediated harm. These patients are most likely to benefit from intervention.

Whether hyperglycemia should be addressed or left untreated has never been evaluated by any prospective clinical trial.

Glucose Measurement

Until recently, intermittent blood glucose levels (using point of care, blood gas analyzer, or central laboratory measurement) were the only means of blood glucose monitoring. Accuracy is probably the most important metric in selecting the best glycemic management device for critically ill children, but rapidity/turnaround time, cost, and sample volume are also important factors.[166] Intermittent measurements are limited by the workload associated with the sampling process and with the potential that "between measurements" events will be missed. A simulation study modeling adult patients on TGC protocol demonstrated that increasing the frequency of glucose measurements reduced the adverse impact of glucose measurement imprecision on glycemic control.[167] A mathematical simulation in a cohort of critically ill patients suggested that glycemic control is more optimal with a blood glucose measurement interval no longer than 1 hour, with further benefit obtained with use of a measurement interval of 15 minutes. These findings have important implications for the development of glycemic control standards and future studies.[168] With growing interest in glycemic control and the possible beneficial effect of frequent glucose measurements, continuous glucose monitoring systems have been developed. Although termed *continuous,* current systems still sample glucose intermittently with a measurement interval of a few milliseconds up to 15 minutes. The Clinical and Laboratory Standard Institute uses 15 minutes as the cutoff for definition of continuous measurement.[169] This frequency may not be sufficient to detect trends and prevent harm in critically ill patients.

One of the key advantages of continuous glucose monitoring is the ability to identify and display trends in blood glucose measurements. High-quality continuous glucose monitoring devices enable us to assess the complexity of the glycemic signal—how one point in time changes relative to neighboring measurements.[170] The clinical significance of these datasets in the pediatric population is unknown at this time. Continuous glucose monitoring has the potential to improve blood glucose control and patient outcome. Continuous glucose monitoring mandates new approaches to the analysis of parameters of glucose regulation. Different goals can be achieved including maintenance of specified target range, avoidance of hypoglycemia, assessment of glucose variability, and determining the degree of glucose complexity.[171]

Future Directions

TGC with intensive insulin therapy in the pediatric population remains controversial. Large multicenter studies with intensive insulin therapy and continuous glucose monitoring are necessary in order to determine whether this strategy can improve outcome. Hypoglycemia rate has been reported and discussed, but other domains of the glycemic control (glucose variability and complexity) have not. In a retrospective analysis of prospectively collected data from more than 3000 adult patients with ICU LOS of longer than 1 day, it was shown that time in blood glucose range of 70 to 140 mg/dL was strongly associated with survival independently of ICU LOS and severity of illness.[172] Current clinical practice and future studies may need to consider methods to define the ideal age-appropriate glucose range and improve the time each patient spends within that range. Most studies reported in the literature have focused on insulin therapy for hyperglycemia. A different potential direction would be to use other medications that may improve glycemic control with lower risk for hypoglycemia and glucose variability.[173,174]

Hypoglycemia

Although the determination of which glucose levels represent hypoglycemia is controversial, a glucose level less than 40 mg/dL is generally accepted to be in the hypoglycemic range. However, this concentration is well below the level at which counterregulatory responses occur. As plasma glucose levels reach 80 to 85 mg/dL, insulin secretion decreases, and as levels approximate 65 mg/dL, glucagon, epinephrine, cortisol, and growth hormone are released.[175] In addition, a decrease in mental efficiency may be seen when levels fall below 50 to 60 mg/dL. Because a delay in the recognition and management of hypoglycemia may lead to long-term neurologic sequelae,[176] it is important to make a distinction between the laboratory diagnosis of hypoglycemia (<40 to 50 mg/dL) and an interventional threshold at which therapies to raise serum glucose should be applied. Setting the interventional threshold at a level similar to that which elicits counter-regulatory responses seems appropriate, and as such, treatment should be offered for hypoglycemia when levels fall below 60 mg/dL to prevent complications, especially in young children. An even higher interventional threshold (<70 mg/dL) is warranted for children who are at increased risk of hypoglycemia.

Clinical Manifestations

Diaphoresis, tremor, tachycardia, anxiety, weakness, hunger, nausea, and vomiting are all autonomic manifestations caused by the adrenergic stress response that occurs with a rapid decline in blood glucose levels. Other symptoms associated with hypoglycemia are a result of a deficiency of the brain's primary energy substrate and as such are known as neuroglycopenic symptoms. These symptoms include headache, visual disturbances, lethargy, restlessness, irritability, dysarthria, confusion, somnolence, stupor, coma, hypothermia, seizures, and motor and sensory disturbances. The glycemic ranges at which these symptoms manifest vary, as critically ill patients cannot recognize or communicate symptoms. The picture is further masked by sedation and analgesia.

Pathogenesis

Imaging studies of infants who sustained neonatal hypoglycemic brain injury display diffuse cortical and subcortical white matter damage that is most prominent in the parietal and occipital lobes. This pattern differs from the neuroimaging features of other neonatal insults, including hypoxic-ischemic encephalopathy.[177] Interestingly, this pattern does not resemble the glucose uptake pattern of neonatal brains by positron emission tomography, which may indicate that neuronal damage is not simply due to cerebral deprivation of its primary substrate for energy production. Evidence indicates that hypoglycemia activates receptors for excitatory amino acids within the brain and causes cell depolarization, with subsequent cellular edema and apoptosis.[178]

Fasting Adaptation

Consumption of glucose is largely dependent on the brain-to-body ratio. This phenomenon explains the reduced fasting tolerance of infants whose glucose utilization rate (approximately 6 mg/kg/min) is significantly higher than that of older children and adults (1 to 2 mg/kg/min). This reality places younger patients at increased risk of hypoglycemia. In addition, their ability to maintain euglycemia through glycogenolysis and gluconeogenesis is reduced because glycogen stores and muscle bulk are small, thus reducing the pool of available gluconeogenic substrates. Within the brain, astrocytes but not neurons are capable of storing glycogen. The brain contains <1 mmol/kg of free glucose reserve. Fasting tolerance increases rapidly in the first days of life. Neonates may fast up to 18 hours after 1 week of age. By 1 year a 24-hour fast is tolerated, and by 5 years a child may fast for up to 36 hours without experiencing hypoglycemia.

Understanding fasting physiology is crucial to the logic and methodologic approach required for diagnosing the etiology of hypoglycemia. Normally in the postabsorptive state, metabolism is governed primarily by counterregulatory hormones. In the first 4 hours of a fast in infants or in the first 8 hours in older children, glucagon is released and euglycemia is maintained primarily by glycogenolysis. Following glycogen store depletion, gluconeogenesis gains importance in the maintenance of normal glucose levels (Fig. 85.6).

Muscle provides amino acids, particularly alanine and glutamine, as gluconeogenic substrates. Glycerol 3-phosphate derived from triglyceride hydrolysis is also a gluconeogenic precursor. Fatty acids resulting from triglyceride hydrolysis are transported to the liver, where they are oxidized to generate acetyl coenzyme A and ketones. The latter may then be used as alternative fuel by skeletal and cardiac muscle to help ensure availability of glucose to the brain and to erythrocytes that are strictly dependent on glucose for energy production. The brain may also use ketones as an alternative fuel source, but it does so only during a prolonged fast (see also Chapter 87).

Hypoglycemia that occurs early during fasting may indicate hormonal imbalance or a primary disorder of glycogenolysis. Disorders of gluconeogenesis will not manifest during early fast. They become apparent only after glycogen stores have been depleted; hence typically they present later in infancy once feeding intervals become increasingly prolonged. The same is true for fatty oxidation disorders. These disorders generally require a more prolonged fast to manifest, nearing 12 to 18 hours

in infants and 18 to 24 hours in older children. A comprehensive approach to diagnosing pediatric hypoglycemia is provided in Chapter 82. However, the most common cause of childhood hypoglycemia is ketotic hypoglycemia.[179] This illness most frequently occurs in toddlers and preschoolers and is uncommon after 8 to 9 years. It is typically triggered by intercurrent infection and caloric restriction, both common events in the PICU. A defect in protein catabolism, transamination, or amino acid efflux from skeletal muscle, as well as impaired autonomic regulation of epinephrine secretion, has been postulated.

Hypoglycemia has been observed in association with a variety of critical illness diagnoses, including sepsis, congestive heart failure, renal failure, liver failure, and pancreatitis, and it has been associated with increased mortality among critically ill children.[180,181] Critically ill patients are at risk of hypoglycemia, not only because of their underlying illness but because of factors unique to their hospitalization, such as muscular atrophy from prolonged immobilization and gluconeogenic substrate depletion, undernutrition often resulting from the limitation of caloric intake because of fluid restriction, increased glucose consumption, adrenal insufficiency, loss of IV access or inadvertent disconnection of infusion lines, or iatrogenic factors related to drugs and therapies, including the practice of strict glycemic control.

Hypoglycemia Treatment

After obtaining the "critical" blood/urine samples (see also Chapter 82), administration of 2 mL/kg of 10% dextrose water solution is indicated for patients with hypoglycemia. Subsequently, an IV maintenance fluid regimen should be initiated to provide a glucose infusion rate of 8 mg/kg/min. Serum glucose should be rechecked 15 minutes after the initial bolus, and if hypoglycemia persists, a bolus of 5 mL/kg of 10% dextrose water should be administered and the glucose infusion rate increased by 50%. If the volume of fluid required to maintain glucose concentrations greater than 70 mg/dL is excessive, a higher dextrose concentration should be used. Glucagon (0.03 mg/kg for patients <20 kg, or 1 mg for patients >20 kg) can reverse hypoglycemia in patients with adequate glycogen stores and normal glycogenolytic pathways. Definitive treatment will depend on the underlying etiology.

In summary, hypoglycemia is a manifestation of iatrogenic, intentional, or accidental drug ingestion or administration or the manifestation of an underlying disorder. All critically ill patients with hypoglycemia should raise a high index of suspicion because many defects that cause hypoglycemia remain silent until an intercurrent illness or stress overwhelms the compensatory capacity of the individual. Unless certitude of the etiology of the hypoglycemia exists before therapy, a "critical" blood/urine sample should be obtained to guide diagnosis and further management. Prompt recognition and treatment are necessary to prevent neurologic injury. A multidisciplinary approach is often necessary.

Alterations of Thyroid Hormone in Critical Illness

Thyroid Biochemistry

Thyroid-stimulating hormone (TSH) derived from the anterior pituitary is a

pleotropic hormone that modulates all aspects of thyroid hormone synthesis.[182] TSH action within the thyroid follicular cells facilitates the sodium iodide symporter, resulting in (1) enhanced iodine concentration in the thyroid gland; (2) increased synthesis of thyroglobulin, the site of tyrosine residues destined for iodination; and (3) activated thyroid peroxidase that catalyzes iodination of tyrosine residues, as well as tyrosine coupling. It is important to note that autoantibodies may bind to TSH receptors and stimulate a response similar to TSH, resulting in a hyperthyroid state. Leptin is likely to mediate an important role in the regulation of the thyroid axis, as suggested by the close correlation between the circadian rhythm of leptin secretion and TSH.[183]

An overview of thyroid hormone biosynthesis and secretion is provided in Fig. 85.7.[13] In this schematic diagram, iodide is transported into the thyroid follicular cell by the action of the sodium-iodide symporter (NIS). Subsequently, this iodide diffuses passively through the iodide channel termed *pendrin* (P). Thyroglobulin (TG) is synthesized within the rough endoplasmic reticulum (ER) and subsequently packaged by the Golgi apparatus into thyroglobulin secretory vesicles that are released into the follicular cell lumen. Thyroid oxidase (TO) produces hydrogen peroxide that is subsequently used by thyroid peroxidase (TPO) to oxidize iodide to iodine, which subsequently reacts with the tyrosine residues within thyroglobulin to produce monoiodotyrosine (MIT) and diiodotyrosine (DIT) residues within the thyroglobulin peptide.

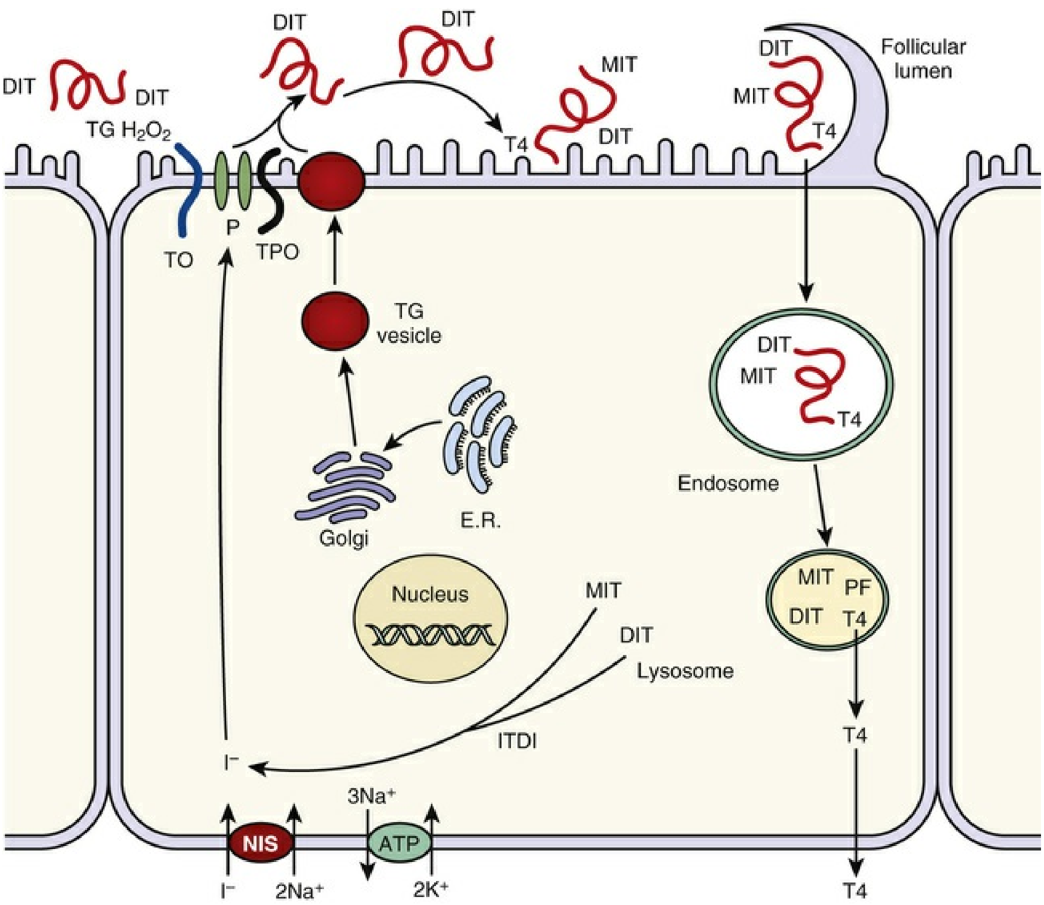

FIG. 85.7 Thyroid hormone biosynthesis and secretion (abbreviations explained in text). (From Goodman HM. Basic Medical Endocrinology. Boston: Elsevier; 2009, p 45.)

Thyroid peroxidase also catalyzes coupling of adjacent iodotyrosines to form thyroxin (T4), as well as lesser amounts of triiodothyronine (T3). Secretion of thyroxin from the thyroid follicular cell begins with thyroglobulin phagocytosis with a subsequent fusion of thyroglobulin endosomes containing proteolytic enzymes capable of digesting thyroglobulin to peptide fragments (PF), as well as monoiodotyrosine, diiodotyrosine, and thyroxin. While thyroxin is released from the cell at the basal membrane, both monoiodotyrosine and diiodotyrosine are deiodinated by iodotyrosine deiodinase (ITDI) and subsequently recycled (see Fig. 85.8).

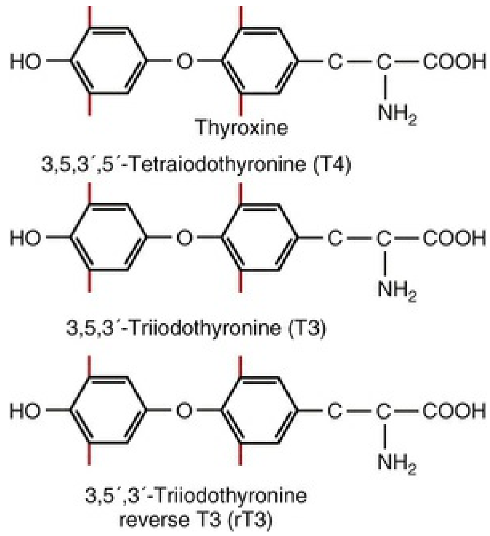

FIG. 85.8 Thyroid hormone chemical structures. (From Goodman HM. Basic Medical Endocrinology. Boston: Elsevier; 2009, p 44.)

Thyroxine is transported to peripheral tissues via transport hormones thyroxine-binding globulin, transthyretin, and albumin. Because all of the thyroxine transport proteins are moderate sized, thyroxine is not filtered by the kidney.

In peripheral tissues, thyroxine (T4) is metabolized to triiodotyrosine (T3) and reverse T3 (rT3) by the action of various isoforms of iodothyrosine deiodinases.[184] Transcription and translation of this enzyme are highly dependent on cytokine stimulation. Selenocysteine residues characterize the active site of this iodine cleavage enzyme. As indicated in Fig. 85.8, if monodeiodination occurs on the outer tyrosine ring, the product is T3, and if the monodeiodination occurs on the inner tyrosine ring, the resultant product is rT3.[13]

In peripheral tissues, T3 binds to thyroid hormone receptors that subsequently undergo homodimerization with other thyroid hormone receptors or heterodimerization with retinoid receptors. Thyroid hormone receptors can bind to specific nucleotide sequences termed *thyroid responsive elements* within promoter regions of genes that they regulate whether or not the thyroid hormone is present. Presence or absence of T3 on the thyroid receptor dictates a corepressor or coactivator activity.[185]

Thyroid Hormone Actions

Box 85.1 summarizes the effects of thyroid hormone on metabolism.[186]

Box 85.1

Thyroid Effects on Metabolism

1. Increased oxygen consumption

2. Enhanced thermogenesis

3. Accelerated amino acid and lipid metabolism

4. Facilitated water and ion transport

5. Enhanced tissue growth and development

6. Altered cortisol and insulin catabolism

7. Modulated growth hormone and parathormone activity

8. Enhanced respiratory response to hypoxia and hypercarbia

9. Increased β-adrenergic receptor affinity and responsiveness to catecholamines

Thyroid hormone significantly affects skeletal and central nervous system growth and maturation. Unrecognized hypothyroidism in infancy results in marked physical, motor, and mental delay termed *cretinism.*[187] Hemodynamically thyroid hormone is known to increase beta-adrenergic receptor density and activity, as well as upregulate genes encoding calcium channels (ryanodine receptor) and sodium potassium ATPase. In a general way, thyroid hormone provides gain control for carbohydrate and lipid metabolism and significantly accelerates both protein synthesis and degradation. Through its effects on uncoupling of ATP production, thyroid hormone can significantly affect energy metabolism and homeostasis, as well as heat production.[188,189]

Hyperthyroidism

Manifestations of thyrotoxicosis reflect increased thyroid hormone concentration, and thyroid storm represents the most severe manifestation of hyperthyroidism. Grave disease is probably the best known example of hyperthyroidism and classically is associated with a diffusely enlarged thyroid gland (goiter), exophthalmos, and cardiac palpitations. Pathophysiology of Grave disease involves thyroid-stimulating autoantibodies that bind to TSH receptors.[190] Hypertrophy and hyperplasia of the thyroid accompanying Grave disease are associated with lymphocytic infiltration.[191] Grave disease typically occurs in adults and chronically is associated with nervousness, fatigue, tremor, heat intolerance, and weight loss.[192] Clinical Grave disease can also occur via increased production of TSH secondary to a pituitary adenoma. Painful thyroiditis (DeQuervain) can occur following a viral illness and be associated with hyperthyroidism.[193] A more likely presentation of hyperthyroidism in a teenager is likely to be caused by Hashimoto thyroiditis.[194]

Amiodarone with a structure similar to thyroxine can be associated with either hyperthyroidism or hypothyroidism.[195]

Patients admitted to the ICU with exaggerated hyperthyroidism (thyrotoxicosis) will typically exhibit either sinus tachycardia or supraventricular tachycardia, nausea, vomiting and diarrhea, weakness, as well as confusion, delirium, or even coma.[196] Classic findings of a diffusely enlarged thyroid with a overlying bruit or murmur may not be present. Neonatal thyrotoxicosis is similar to Grave disease and involves transplacental passage of TSH-like autoantibodies from the mother to the fetus. Thyrotoxicosis pathophysiology is more common among patients with Down syndrome, diabetes mellitus, and McCuen Albright syndrome. Signs and symptoms of thyrotoxicosis are summarized in Box 85.2.

Box 85.2

Signs and Symptoms of Thyrotoxicosis

1. Hyperactivity, tremor, agitation, hyperreflexia
2. Sinus tachycardia, palpitations, arrhythmias, systolic hypertension, heart failure
3. Perspiration
4. Abdominal pain, diarrhea
5. Bulging eyes (exophthalmos)
6. Thirst
7. Proximal myopathy
8. Apathy, stupor, coma

Treatment of thyroid storm involves a four-pronged approach: (1) controlling thyroid gland production of T4 using thionamides such as propylthiouracil and methimazole, which interfere with thyroid peroxidase iodination; (2) blocking T3 activity in peripheral tissues using thionamides, iopanoic acid, beta-adrenergic blockage, and corticosteroids; (3) providing supportive measures such as antipyretics, anxiolytics, and volume resuscitation as needed; and (4) identifying and treating identifiable precipitating antecedents. In severe cases of recalcitrant thyroid storm, plasmapheresis with charcoal hemoperfusion has been used to reduce circulating thyroxine.[197] Occasionally, subtotal thyroidectomy may be required for chronic thyrotoxicosis. Postsurgical complications in such patients that intensivists should anticipate include recurrent laryngeal nerve damage, hypocalcaemia with tetany secondary to inadvertent parathyroid gland resection, and hypothyroidism.[198]

Hypothyroidism

The most common cause of hypothyroidism is iodine deficiency, affecting approximately 800 million people worldwide.[199] As noted previously, unrecognized

neonatal hypothyroidism is of particular concern given the consequences if appropriate intervention is not initiated. In the PICU, Down syndrome children with unstable hemodynamics following cardiovascular surgery should be particularly suspect for hypothyroidism. Signs and symptoms of neonatal hyperthyroidism include prolonged neonatal jaundice, coarse features, protruding tongue, apathy, poor feeding, and umbilical hernia. True hypothyroidism secondary to thyroid gland failure or maldevelopment will manifest with an elevated TSH concentration, although this response may be blunted in the ICU by malnutrition and administration of dopamine and corticosteroids.

Euthyroid Sick Syndrome in Critical Illness

As previously noted, monodiodination of the inner tyrosine residue of thyroxine leads to production of reverse T3. Euthyroid sick syndrome is characterized by a rapid decrease in T3 and variable increase in rT3 that appears to be proportional to the intensity of illness severity and concentration of TNF-α.[200] In addition, a decline in various thyroid hormone-binding proteins is evident. Conversion of T4 to T3 is suppressed secondary to decreased 5′-deiodinase activity. Because of decreased thyroid-releasing hormone (TRH) gene expression in the hypothalamus, TRH is decreased with a resultant reduced TSH messenger RNA. Euthyroid sick syndrome (nonthyroidal illness syndrome) has been detailed among pediatric cardiac surgery patients.[201,202] Laboratory finding characteristics of euthyroid sick syndrome are summarized in Table 85.3.[203]

TABLE 85.3

Euthyroid Sick Syndrome Laboratory Data

Variable	Value
Free T4	Normal
T4 → T3 Conversion	Decreased
T3	Markedly decreased
rT3	Variable
TSH	Normal

Significance of euthyroid sick syndrome in critical illness remains controversial. Evidence indicating overt pathology in this setting is sparse. Some argue that this scenario reflects an effort of the body to conserve energy expenditure during one aspect of the stress response (see Chapter 81). Thyroid hormone alterations characteristic of euthyroid sick syndrome would also be expected to modulate protein catabolism.[204] Euthyroid sick syndrome should be differentiated from true hypothyroidism. The latter can occasionally occur among patients administered dopamine and high-dose corticosteroids, both secondary to inhibition of TSH. Various drug effects on thyroid hormone metabolism are summarized in Table 85.4.

TABLE 85.4

Effects of Various Drugs on Thyroid Hormone Metabolism

Drug	Effect
Dopamine	Blunts TSH response to TRH
Corticosteroids	Suppresses basal and TRH-stimulated TSH release
Iodinated contrast agents	Decreases hepatic conversion of T4 to T3

Amiodarone	Decreases hepatic conversion of T4 to T3 and decreases servo feedback T3 binding at the pituitary
Phenytoin	Enhances T4 to T3 conversion (low free T4 and low total T4)

TRH, thyroid-releasing hormone; *TSH*, thyroid-stimulating hormone.

Thyroid Hormone Supplementation in PICU

Patients with true hypothyroidism should obviously receive replacement thyroxine. Treatment of euthyroid sick syndrome is more controversial. Although the basis for the observation is not clear, adult investigators have previously demonstrated that low serum T3 levels represent the single most significant predictor of cardiovascular and all-cause mortality among adults with heart disease.[205] Triiodothyronine replacement in adults with impaired left ventricular function resulted in improved left ventricular function, as well as restored cardiomyocyte gene expression to euthyroid levels.[206] Among adult patients with heart failure, infusion of T3 for 72 hours resulted in normalization of serum T3 levels with concomitant improvement in stroke volume, as well as left ventricular end-diastolic volume.[207] Such findings have stimulated interest in thyroid hormone pathophysiology among children with cardiovascular disease. Thyroid function and clinical outcomes were assessed serially among children undergoing cardiac bypass surgery. All subjects demonstrated euthyroid sick syndrome characterized by reduced TSH, total T3, free T3 index, and T3 uptake. These changes were correlated with prolonged need for mechanical ventilation, degree of organ dysfunction, and vasoactive-inotropic scores.[208]

One interventional trial reported the effect of T3 supplementation among children undergoing cardiovascular surgery. In this investigation, replacement dosing of T3 following cardiopulmonary bypass resulted in increases in plasma T3 concomitant with measures of improved myocardial performance, particularly among those children exhibiting low postoperative cardiac output.[209] A subsequent multicenter, double-blind, randomized, placebo-controlled trial enrolling children younger than 2 years old undergoing cardiac surgery requiring cardiopulmonary bypass examined the effect of IV T3 ($n = 98$) or placebo ($n = 95$). Overall the primary outcome, time to tracheal extubation, was similar between groups. However, for patients younger than 5 months, the hazard ratio (chance of extubation) for extubation was 1.72 (P = 0.0216), with median time to extubation in the T3 group 55 hours compared with 98 hours in the placebo group. Shorter duration of mechanical ventilation corresponded to a reduction in inotropic agent use and improvement in cardiac function. There were no differences in adverse event rates, including arrhythmia between groups.

Acknowledgment

The authors acknowledge the considerable contributions of Dr. Kalia Ulate for this chapter in the fourth edition of *Pediatric Critical Care.*

CHAPTER 86

Diabetic Ketoacidosis

Ildiko H. Koves, Nicole Glaser

PEARLS

- Diabetic ketoacidosis (DKA) results either from absolute insulin deficiency or from relative insulin deficiency in the setting of high levels of counterregulatory hormones stimulated by infection or other illness.
- DKA is characterized by hyperglycemia, ketosis, and acidosis.
- Treatment of pediatric DKA involves intravenous insulin administration, intravenous fluid administration to correct dehydration, and replacement of electrolyte deficits.
- Cerebral edema is the most frequent serious complication of DKA in children and is the most frequent cause of morbidity and mortality resulting from DKA.

Etiology, Definition, and Presentation

Diabetic ketoacidosis (DKA) occurs when serum insulin concentrations are very low in relation to concentrations of glucagon and other counterregulatory hormones (epinephrine, norepinephrine, cortisol, and growth hormone). This situation occurs most commonly in new onsets of type 1 diabetes mellitus (T1DM) and in patients with known diabetes during infections or other intercurrent illnesses or with insulin omission (discussed later). In the setting of low insulin concentrations in relation to counterregulatory hormone concentrations, the normal physiologic mechanisms responsible for maintaining adequate fuel supply during fasting and physiologic stress are exaggerated, resulting in hyperglycemia, ketosis, and acidosis. A diagnosis of DKA can be made when the serum glucose concentration is greater than 200 mg/dL (>11 mmol/L) and venous pH is less than 7.30 (or the serum bicarbonate concentration is less than 15 mmol/L) in the presence of elevated urine or serum ketone concentrations.

In a child with new onset of T1DM, declining insulin production results from autoimmune destruction of pancreatic beta cells. The concentration of insulin is decreased relative to glucagon causing excess hepatic glucose production and decreased peripheral glucose uptake in muscle and adipose tissue.[1,2] When the serum glucose concentration rises above approximately 180 to 200 mg/dL, the renal threshold for glucose reabsorption is exceeded causing glycosuria, which leads to

osmotic diuresis and compensatory polydipsia. Low insulin concentrations also stimulate the release of free fatty acids (FFAs) from adipose tissue to fuel ketogenesis.[3] This, in combination with activation of the hepatic β-oxidative enzyme sequence resulting from relative excess of glucagon in relation to insulin, results in markedly increased hepatic ketone production.[2-4]

Progressive dehydration and increasing acidosis eventually stimulate release of the counterregulatory ("stress") hormones, cortisol, catecholamines, and growth hormone, which accelerate hepatic glucose output and ketone production.[5,6] Infection or other illness or injury can likewise contribute to this process by stimulating release of counterregulatory hormones. Elevated cortisol concentrations augment FFA release from adipose tissue and decrease peripheral glucose uptake. Increased epinephrine concentrations directly increase glycogenolysis and stimulate the release of gluconeogenic precursors from muscle.[7,8] Both epinephrine and norepinephrine also stimulate lipolysis and β-oxidation of FFAs.[9,10] Catecholamines may also directly inhibit insulin secretion, thereby accelerating DKA in those with endogenous insulin capacity, such as those with a new diagnosis of T1DM or those with type 2 diabetes.[11,12] Growth hormone also decreases peripheral glucose uptake and enhances ketone production by increasing FFA release.[13] Elevated concentrations of counterregulatory hormones thus result in increased acidosis, hyperglycemia, and dehydration. This in turn stimulates further counterregulatory hormone release, thereby creating a vicious cycle resulting in rapid worsening of DKA (Fig. 86.1).

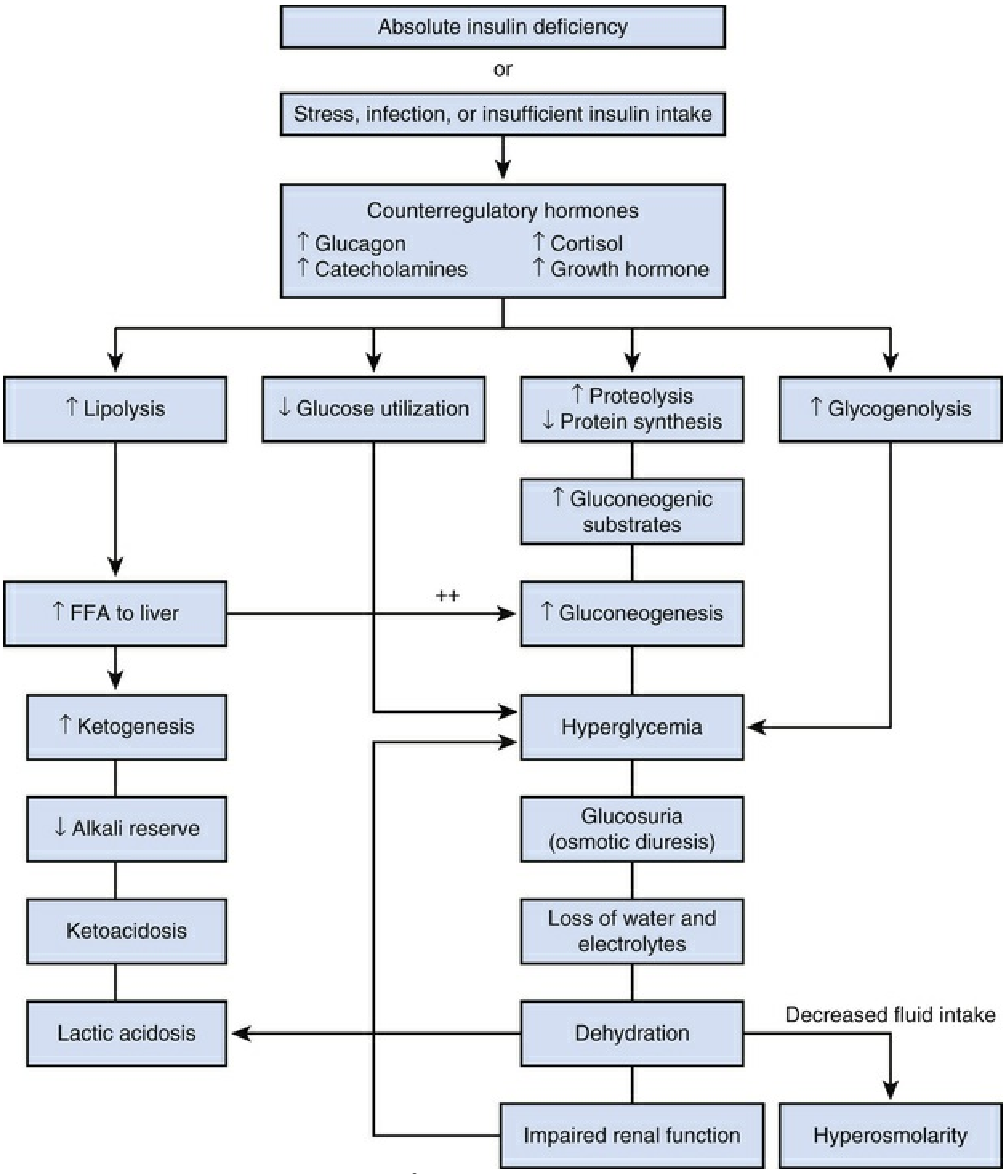

FIG. 86.1 Pathophysiology of DKA. (Reprinted with permission from Wolfsdorf J, Glaser N, Sperling MA. Diabetic ketoacidosis in infants, children, and adolescents: a consensus statement from the American Diabetes Association. Diabetes Care. 2006;29:1150-1159.)

During DKA, intestinal ileus results from potassium depletion, acidosis, and diminished splanchnic perfusion, causing abdominal pain and vomiting and thereby limiting fluid intake. Progressive dehydration eventually leads to diminished tissue perfusion sufficient to cause an accumulation of lactic acid, enhancing acidosis.[14] In addition, poor perfusion may result in diminished renal function, limiting the capacity for clearance of glucose and ketones. Ongoing osmotic diuresis and ketonuria in the setting of acidosis also results in urinary losses of electrolytes (potassium, sodium, chloride, calcium, phosphate, and magnesium).

Classical symptoms of DKA include polyuria, polydipsia, polyphagia, weight loss, abdominal pain, nausea, and vomiting. Abdominal tenderness, absence of bowel sounds, and guarding are frequent and may even mimic the acute abdomen.[15] Tachycardia and signs of hypoperfusion, such as delayed capillary refill time and cool extremities, are also common as well as dry mucous membranes, absence of tears, and poor skin turgor. Despite substantial volume depletion, however,

hypotension is unusual in children with DKA and occasional children may present with hypertension. Kussmaul breathing and tachypnea are the result of metabolic acidosis and respiratory compensatory mechanisms. Fruity breath odor (acetone) may be present. Hypothermia has also been described.[16]

Although hyperglycemia is part of the definition of DKA, in rare cases, the serum glucose concentration may be nearly normal, so-called euglycemic DKA. This situation has been reported most frequently in pregnant women.[17-19] Normal glucose concentrations or even hypoglycemia despite ketosis may also occur in children with known diabetes who administer insulin to treat DKA prior to arrival in the emergency department. In general, however, the persistence and severity of hyperglycemia reflect the severity of dehydration. In the absence of preexisting renal disease or unusually high carbohydrate intake just prior to presentation, blood glucose concentrations in excess of 500 to 600 mg/dL imply that dehydration is of sufficient severity to diminish the glomerular filtration rate and thereby diminish the capacity for renal clearance of excess glucose.[20]

Concentrations of ketone bodies (beta-hydroxybutyrate [βOHB] and acetoacetate [AcAc]) are elevated in DKA resulting in acidosis. Hyperchloremic acidosis frequently coexists with increased anion-gap acidosis, and the anion gap reflects the combination of these processes.[21] The ratio of βOHB:AcAc (typically 1 : 1 in the normal state) is increased during DKA and may be as high as 10 : 1.[22] During treatment, this ratio returns to normal. The nitroprusside reaction used to test urine ketone concentrations detects only AcAc and not βOHB. As a result, urine testing cannot be relied on to determine DKA severity or treatment response. Bedside blood ketone meters provide a rapid means for measuring βOHB and may be useful in place of or in addition to urine testing particularly in patients with anuria or oliguria who produce insufficient amounts of urine for ketone testing.[23] Blood ketone measurements are also useful for determining the timing of transition from intravenous to subcutaneous insulin administration. Urine ketones may be present even when blood ketones have normalized as a result of urine stagnating in the bladder.

Hyperglycemia results in fluid shifts from the extravascular to the intravascular space and a decrease in the serum sodium concentration. This decrease can be calculated as an approximately 1.6 mEq/L decrease in sodium concentration for every 100 mg/dL increase in serum glucose above 100 mg/dL ($Na_{\text{corrected}} = Na_{\text{actual}} +$ [glucose-5.5 mmol/L]).[24,25] Hyperlipidemia may also contribute to a decrease in measured serum sodium concentrations.[26] Typically, serum potassium concentrations at presentation are in the high-normal range as a result of the redistribution of potassium ions from the intracellular to the extracellular space. Several processes are responsible for intracellular potassium depletion including direct effects of low insulin concentrations, intracellular protein and phosphate depletion, and buffering of hydrogen ions in the intracellular compartment.[27] Intracellular potassium stores may be profoundly depleted, and the serum potassium concentration typically declines rapidly with insulin treatment. Serum phosphate concentrations similarly decrease during treatment.

Leukocytosis is frequent in children with DKA, likely resulting from elevated concentrations of catecholamines and pro-inflammatory cytokines. In children, new onsets of T1DM or insulin omission are far more common causes of DKA than infection.[28] Therefore, an elevated or left-shifted white blood cell count need not

prompt a search for an infectious process in the absence of fever or other symptoms or signs of infection. However, in the presence of fever, careful history, physical examination, and laboratory evaluation to assess for infection are prudent (Table 86.1).

TABLE 86.1

Laboratory Monitoring Schedule Recommendation

Laboratory Analysis	DKA Confirmed	Hour 1	Hour 2	Hour 3	Hour 4	Hour 5	Hour 6	Hour 7	Hour 8	Hour 9	Hour 10	Hour 11	Hour 12
Glucose[a]	X	X	X	X	X	X	X	X	X	X	X	X	X
Sodium[b]	X	X	X		X		X		X		X		X
Potassium	X		X		X				X				
Chloride	X		X		X				X				
Bicarbonate	X		X		X				X				
BUN	X												
Creatinine	X												
Magnesium[c]	X				X				X				
Calcium[c]	X				X				X				
Phosphorus[c]	X				X				X				
Blood gas (capillary blood gas, venous blood gas, arterial blood gas)	X				X								
β-hydroxybutyrate[b]	X		X		X		X		X		X		X
Blood culture[d]	X												
Urinanalysis[d]	X												

[a]Repeat glucose every hour while on insulin drip; send first glucose to the lab as well for serum glucose.

[b]Repeat sodium and β-hydroxybutyrate (BOHB) every 2 hours while on insulin drip.

[c]May repeat these labs every 4 hours until normalized, especially while on insulin drip.

[d]Only if febrile or concern for infection, and do not repeat if done at referral hospital.

Epidemiology

Frequency of Diabetic Ketoacidosis at Diagnosis

The frequency of DKA at diagnosis varies widely by geographic region, with an overall estimated frequency of approximately 20% to 67%. In the population-based US study SEARCH for Diabetes in Youth, data were collected from self-reported health questionnaires and medical record review. In this study, 36.4% of children and adolescents presented at the onset of diabetes in DKA.[29,30] The frequency of DKA varies depending on regions: 26.3% in a collaborative cohort in Germany and Austria 21.1%[31]; Swedish data report 16.9%; and Finnish registers report 18.7%.[32] Younger age (<5 years) and female sex were associated with higher likelihood of presenting in DKA.[33,34] A delay in diagnosis is associated with a higher likelihood of DKA, and two factors contributing to this result are patient age and provider experience. Regions with a higher prevalence of T1DM generally have a lower frequency of DKA,[35] attributed to heightened awareness in providers and thus earlier detection. Interestingly, however, three of The Environmental Determinant of Diabetes in the Young (TEDDY) study participant families who were counseled on diabetes symptoms nonetheless presented with DKA.[36] The nonspecific nature of individual symptoms, such as polyuria, tachypnea, and altered mental status, may cause such symptoms to be misconstrued as urinary tract infection, pneumonia, or

meningitis, respectively.[37] Mallare and colleagues reported a frequency of DKA of 33% in children and adolescents at the initial visit and almost double (59%) in those in whom the diagnosis of diabetes was missed at the initial visit. The diagnosis of diabetes was more likely to be missed in very young children (34% of children ≤5 years of age compared to 8.5% in those older than 10 years of age),[38] particularly when these very young children are evaluated by family practitioners rather than pediatricians.[39] Usher-Smith and coworkers found protective factors of a first-degree relative with T1DM, higher parental education, and higher background incidence of T1DM in a systemic review of 46 studies involving 24,000 children from 31 countries.[40]

Frequency of Diabetic Ketoacidosis in Children and Adolescents After Diagnosis

Although there are several population-based studies reporting the frequency of DKA at presentation, fewer data are available describing the incidence of DKA in children and adolescents with established diabetes. Reported frequencies range from 1 to 10 per 100 patient-years.[41] In the Diabetes Control and Complications Trial, the incidence of DKA in adolescents treated with intensive management regimens was 2.8 per 100 patient-years, significantly lower than the incidence in those treated conventionally (4.7 per 100 patient-years). Although this is an older study, it was a time- and resource-intensive study and represents a more idealized situation than often encountered in the overall pediatric diabetes population.[42] In a more recent study from the Barbara Davis Center for Childhood Diabetes in Denver, Colorado, the overall incidence of DKA was 8 per 100 person-years. In that study, factors associated with higher incidence included older age, higher HbA1C (relative risk [RR] of 1.68 per 1% increase in HbA1C in younger children, RR of 1.43 in older children), higher reported insulin dose, DSM4 psychiatric diagnoses, and "underinsurance" reflected lower socioeconomic status.[43] DKA is also observed more often in children and adolescents on continuous subcutaneous insulin infusion therapy (CSII) than on subcutaneous injections, particularly in the first year of initiation of CSII.[44] However, lower rates of DKA are achievable for those on CSII with adequate training and resources.

T2DM has been occurring with increasing frequency in older children and adolescents. Certain racial/ethnic groups in the United States are disproportionately affected, including Native Americans, Hispanics, and African Americans. DKA can be the clinical presentation of T2DM in youth estimated at 5% to 10%.[45] Youth with T2DM may also present with hyperglycemic hyperosmolar state (HHS), also referred to hyperosmotic hyperglycemic nonketotic coma (HHNK, described more fully later).

Morbidity and Mortality Associated with Diabetic Ketoacidosis

Mortality in children presenting with DKA is approximately 0.25% to 0.30%.[41] Most of the mortality in DKA occurs in children with cerebral edema, accounting for 57% to 87% of deaths. Neurologic sequelae of DKA are described later. Other causes of morbidity and mortality include sepsis and secondary infection, electrolyte

abnormalities (eg, hypokalemia), arrhythmias, rhabdomyolysis, cerebral infarction, thrombosis, pneumomediastinum, subcutaneous emphysema, and pulmonary edema.

Management Guidelines (Fig. 86.2)

Fluids

Restoration of adequate peripheral perfusion and hemodynamic stability with bolus administration of intravenous fluids (0.9% saline or other isotonic fluids) should begin as soon as possible. Typical patients require an initial fluid bolus of 10 mL/kg and repeated boluses if ongoing hemodynamic instability is present. Studies have shown that clinical assessments of dehydration severity in children with DKA tend to be inaccurate (Fig. 86.3).[46-48] The average degree of dehydration for most patients is approximately 7% to 9% of body weight, and this figure should be used as a basis for determining the total volume of fluids to be replaced. The estimated fluid deficit, along with maintenance fluid requirements, should be replaced over 36 to 48 hours using 0.45% to 0.90% saline, generally initially with 0.90% saline then transitioning to 0.45% saline after several hours. Replacement of ongoing urinary fluid losses is usually unnecessary because osmotic diuresis typically resolves rapidly after beginning DKA treatment. However, in circumstances of persistently high urine output, or profuse vomiting or diarrhea, replacement of ongoing losses may be considered. Large multicenter studies are under way comparing rapid and slower rehydration regimens.[49] Some guidelines (national and international publication by the International Society of Pediatric and Adolescent Diabetes [ISPAD] British and Australasian Endocrine Group) have favored more gradual rehydration, with attention to effective osmolality,[30,50] but prospective data are lacking at present.

Insulin

Low-dose insulin should be administered intravenously at a rate of 0.05 to 0.10 units/kg/hour. Insulin administration results in resolution of acidosis and hyperglycemia via suppression of ketogenesis and hepatic glucose output and promotion of peripheral glucose uptake. An initial bolus or loading dose of insulin is not recommended. Maximal suppression of ketogenesis is achieved rapidly with an insulin infusion (0.05–0.10 unit/kg/hour).[51-53] Even in the absence of insulin administration, the serum glucose concentration often decreases substantially with initial rehydration, reflecting improvements in renal perfusion and decreased counterregulatory hormone concentrations.[14] This decline in glucose concentration during the initial period of rehydration should not be interpreted as indicating excessive insulin administration.

Serum glucose concentrations typically normalize before ketosis and acidosis resolve. To continue insulin administration at dosages sufficient to allow resolution of ketosis, dextrose should be added to the intravenous fluids. Transition to dextrose-containing fluids should occur when the serum glucose concentrations decline below approximately 250 mg/dL. The “two bag system” for dextrose administration allows a rapid response to changes in serum glucose concentration and is cost effective.[54] Two bags of intravenous fluids with identical electrolyte content, but different dextrose content (0% and 10%), are administered simultaneously with the relative rates of administration frequently adjusted to increase or decrease the dextrose concentration while maintaining a constant overall rate of administration of fluid and electrolytes.

Electrolytes

Serum potassium concentrations often decline rapidly during treatment and potassium replacement is mandatory. Typical patients require potassium administration at concentrations of 30 to 40 mEq (occasionally up to 80 mEq) per liter of intravenous fluids. Potassium chloride may be used alone or in combination with other potassium salts (potassium phosphate or potassium acetate), allowing for lower chloride administration. Adequacy of renal function should be considered before administration of potassium.

Phosphate replacement in children with DKA is controversial. Theoretically, low 2,3-diphosphoglycerate (DPG) levels in red blood cells may occur in association with hypophosphatemia leading to decreased tissue oxygen delivery.[55,56] Occurrence of this effect to a clinically relevant degree, however, has not been shown. Although the risk of hypocalcemia during DKA treatment is increased with phosphate replacement, symptomatic hypocalcemia is uncommon when phosphate is administered slowly and in the more modest concentrations recommended in most DKA treatment protocols.[57,58] Severe hypophosphatemia during DKA has been shown to be associated with rhabdomyolysis and hemolytic anemia, suggesting that monitoring of serum phosphate concentrations is necessary and treatment of severe hypophosphatemia is essential.[59,60]

Hypomagnesemia and hypocalcemia may also occur during DKA treatment but are generally mild, rarely requiring treatment. Monitoring of serum calcium and magnesium concentrations, however, is recommended.

Correction of Acidosis

Routine bicarbonate administration is contraindicated in children with DKA, as acidosis generally corrects rapidly with insulin and fluid administration, and hemodynamic instability resulting from acidosis is rare. Bicarbonate administration is associated with several possible adverse effects including an increase in the risk of hypokalemia and a theoretic increase in tissue hypoxia resulting from a leftward shift in the hemoglobin-oxygen dissociation curve.[55,61] Paradoxical acidosis of the cerebrospinal fluid has also been documented with bicarbonate administration, likely resulting from diminished respiratory drive and a rise in the partial pressure of CO_2, which readily crosses the blood-brain barrier generating CSF acidosis.[62,63] Bicarbonate administration has also been associated with an increased risk of DKA-related cerebral edema.[64] In very rare circumstances (severe hemodynamic instability not responding to standard measures or potentially life-threatening hyperkalemia), bicarbonate administration may be considered.

Monitoring

Intensive monitoring is essential for children with DKA, and most should be treated in a pediatric intensive care unit or other unit with similar capacities.[65,66] Blood glucose concentrations are typically measured hourly and electrolyte concentrations every 2 to 4 hours. Determinations of serum pH (every 2 to 4 hours) are helpful, particularly because serum bicarbonate concentrations may not increase during the first several hours. Free-flowing venous blood gas samples generally are sufficient and arterial samples are rarely needed. Failure of acidosis to improve during treatment should prompt evaluation of the adequacy of insulin infusion, fluid balance, and a search for other causes such as hyperchloremia, renal failure, sepsis, or even appendicitis. Monitoring of the βOHB level during DKA is prudent as its clearance (to <1 mmol/L) provides an end point for ongoing intensive DKA care.[50,67]

All fluid intake and output should be accurately recorded. Consideration of fluids and other management that may have occurred prior to admission to a pediatric intensive care unit is important. Vital signs and mental status should be monitored hourly. One study showed a high frequency of prolonged QT interval corrected for heart rate (QTc) in children with DKA, and arrhythmias have been described in rare cases.[68] Therefore, cardiac monitoring is recommended.

Diabetic Ketoacidosis–Associated Complications

Cerebral edema (CE) has been recognized as a complication of T1DM in children since 1936. It is essentially a clinical diagnosis, based on the deterioration of mental state during resuscitation for DKA. Signs and symptoms that should prompt consideration of CE include the Cushing triad (inappropriate slowing of heart rate, hypertension, and widening pulse pressure), severe headache, recurrence of vomiting, irritability, lethargy, or other mental status changes.[69] Some patients progress to coma, respiratory arrest, and cerebral herniation. Most episodes of CE occur several hours after the initiation of DKA treatment; however, 5% to 20% of cases occur at the time of presentation, prior to the initiation of therapy. Cerebral edema remains the leading cause of death and morbidity in children with T1DM. The frequency of CE associated with DKA remains unchanged despite clinical efforts

to the contrary.[34]

The reported mortality from CE varies widely and is in part dependent on the criteria used to define CE. Rates as high as 50% to 90% have been reported, but more recent studies[64,70] report lower rates of 21% to 24%. Overall, the incidence of CE is approximately 0.7% to 0.9% within DKA presentations. In other words, approximately 1 in 400 children with DKA die as a result of CE. Morbidity is significant; in particular debilitating neurologic sequelae occur in 21% to 26% of children with DKA-related CE.[64,70] Although frank CE is uncommon, there is substantial data to suggest that subclinical or asymptomatic CE occurs in many children with DKA, perhaps even in the majority. Limited data suggest that subtle brain injury may also be associated with DKA, even in the absence of clinically apparent CE.[71]

The pathophysiology of CE remains enigmatic. Several causative theories have been proposed for the occurrence of CE during DKA. Idiogenic, osmotically active substances that regulate cell volume have been thought to play a role in causing DKA-related CE. Taurine, 2-aminoethane sulfonic acid, is thought to have a critical role in neuro-osmoregulation during DKA.[72] Alternatively, cerebral hypoperfusion (caused by hypocapnia and volume depletion) prior to DKA treatment and the effects of reperfusion during DKA therapy have been hypothesized to result in CE and cerebral injury.[73,74] Direct effects of ketone bodies and inflammatory cytokines on blood-brain barrier function, increased activity of brain ion transporters, and activation of brain microglia have also been hypothesized to be involved.[75-78] To date, however, the precise pathophysiology of CE remains unresolved, and multiple factors may be involved with individual susceptibility.

Epidemiologic studies of risk factors for CE show that children with higher initial blood urea nitrogen (BUN) concentrations, lower initial PCO_2 concentrations, and greater acidosis at the time of presentation of DKA seem to be at greatest risk for CE.[64,74,79,80] A lesser rise in measured serum sodium concentration during DKA treatment has also been associated with increased risk of CE, as has treatment with bicarbonate.[64] Early administration of insulin (within the first hour) has also been associated with increased CE risk in one study.[79] Studies evaluating the impact of variations in fluid administration protocols on risk of CE have yielded conflicting results. As yet, there is no clear association between any aspect of fluid treatment and increased risk of CE.

Once the diagnosis of CE is made, treatment is a matter of urgency and should not be delayed while awaiting imaging studies or further testing. Intravenous 20% mannitol (0.25–1 g/kg infused over 15 minutes) should be initiated as soon as possible. Some reports suggest the use of 3% saline in boluses (5 mL/kg over 5–10 minutes) or as a continuous infusion for treatment of CE, but data demonstrating beneficial effects are limited to case reports[81,82] and some reports suggest the possibility of poorer outcomes with 3% saline in comparison with mannitol.[83] Therefore, experts caution against generalized use.[84] Ongoing intensive care unit monitoring is essential. Respiratory support by means of endotracheal intubation is likely to be required due to severe alterations in mental status and impaired airway reflexes. Therapeutic hyperventilation in intubated patients, however, has been associated with poorer outcomes.[85] Therefore, decreasing PCO_2 below the patient's own compensation for metabolic acidosis should be avoided in children with DKA except where absolutely necessary to treat impending cerebral herniation. A

reasonable approach would be to initially maintain the patient's current PCO_2 level and then gradually allow the PCO_2 to increase as acidosis corrects. CNS imaging in patients with suspected CE should be used to exclude other etiologies of altered mental status such as CNS thrombosis or infarction. Imaging may not be necessary if there are improvements after CE therapy.[30,30]

Hyperglycemic Hyperosmolar Syndrome

Hyperglycemic hyperosmolar syndrome (HHS) is characterized by extreme elevations in serum glucose (>600 mg/dL) and hyperosmolarity (serum osm >330 mOsm/kg) in the absence of significant ketosis or acidosis (urine ketone concentration <1.5 mmol/L and serum bicarbonate >15 meq/L). Although HHS is defined as a condition separate from DKA, 30% of cases occur in combination with substantial ketosis and acidosis meeting criteria for both HHS and DKA. Until recently HHS was thought to occur infrequently in pediatrics. An increase in case reports of HHS in children suggests that the frequency may be increasing.[86,87] As in adults, HHS in children has a relatively high mortality of 10% to 35%.[88,89] The majority of HHS reports in children are in patients who have acanthosis nigricans, are obese, are African American, and have a family history of type 2 diabetes. Most cases of HHS are the initial presentation of diabetes, and most of these youths will subsequently have a clinical diagnosis of type 2 diabetes.

The occurrence of HHS during DKA poses challenges in terms of recognition and treatment. Generally dehydration is more profound than the clinical assessment would suggest, reflecting difficulties in clinical evaluation due to obesity and relative preservation of intravascular volume due to hyperosmolarity. Electrolyte losses similarly exceed those of DKA as a result of more prolonged osmotic diuresis. Patients who meet criteria for both DKA and HHS require more prolonged and aggressive fluid and electrolyte replacement therapy than typical children with DKA. Replacement of ongoing urinary losses may be necessary. Frequent reassessment of circulatory status and fluid balance is critical. A high frequency of thrombosis has been described in children with HHS as well as rhabdomyolysis and a malignant hyperthermia-like syndrome.[90,91] Cerebral edema appears to be a rare complication of HHS, with only one case reported.[92]

Thrombotic Complications

Thrombotic complications are common in children with DKA and central venous catheters are particularly prone to thrombosis.[93,94] Cerebral thrombosis and pulmonary emboli have also been described. Hyperosmolarity may result in direct osmotic disruption of endothelial cells leading to a release of tissue thromboplastins.[95] Higher levels of vasopressin stimulated by hypertonicity and decreased vascular volume may also contribute to enhanced coagulation.[96] Prophylaxis with low-dose heparin should be considered for children with central venous lines.[97-99]

Other Complications

Rhabdomyolysis[100,101] is potentially life threatening. It is characterized by elevated

serum creatine kinase, lactate dehydrogenase, and amino alanine transferase concentrations due to muscle injury. Rhabdomyolysis may result in renal failure, compartment syndrome, severe hyperkalemia, and other electrolyte disorders leading to arrhythmias. Hyperosmolarity has been thought to be one causative factor, and the risk is higher in children who have DKA complicated by features of HHS.[100]

Acute pancreatitis has been described in case reports of both children and adults with DKA, but it occurs rarely. Far more frequent are benign elevations in serum amylase or lipase occurring in 24% to 40% of children with DKA. These elevated pancreatic enzyme concentrations typically normalize rapidly with DKA treatment and are not associated with clinical features of pancreatitis.[102]

Although neurologic deterioration in children with DKA is most frequently caused by cerebral edema, cerebral infarctions with and without hemorrhage and cerebral thrombosis have also been described.[103] Other rare complication of DKA in children include pulmonary edema,[104] cardiac arrhythmias,[105] renal failure,[106] intestinal necrosis,[107-109] and rhinocerebral mucormycosis.[110,111]

Neuropsychologic Sequelae

Adverse neurodevelopmental outcomes in children with diabetes have in large part been attributed to recurrent hypoglycemia, and this area has been extensively investigated. Hyperglycemia and hyperglycemic extremes such as occur with DKA have been attracting increasing attention and interest for their potential neuropsychologic sequelae. Short-term effects on neurocognitive performance involving complex skills, such as inhibiting an over-learned response and learning of complex novel information, have been described.[112] Long-term deficits in memory,[71] mental state scores on standardized, validated testing, poorer sustained attention, and poorer delayed memory recall[113] have been found to be associated with DKA.

Health Care Costs Associated With Diabetic Ketoacidosis

Health care costs for DKA vary by geographic regions in the United States, and comparing costs is often complicated by variations in health care systems, methods of reporting costs (eg, hospital costs versus payer costs), and contractual arrangements. Several studies document that admissions for DKA are an important driver of diabetes-related health care costs in the United States.[114-116] In addition, among patients with known diabetes admitted for DKA, readmissions within 1 year of discharge are common.[114] One strategy to decrease the frequency of DKA is to promote awareness in the general population, in communities, and among providers. A successful campaign to heighten awareness of signs and symptoms of DKA took place in Parma, Italy. In the Parma campaign, simple messages regarding signs and symptoms of diabetes were provided to practitioners and schools, and free access to care was arranged. Compared to neighboring regions where the frequency of DKA was quite high at 78%, the Parma region observed a very low frequency of 12.5% during the 8 years of the campaign. Of note, the campaign was relatively inexpensive, costing $23,000 for the 8 years of the campaign.[35]

Another more targeted strategy is linked to recognition of diabetes risk. In

children enrolled in prevention studies (mainly siblings of probands with type 1 diabetes), the frequency of DKA is far less than that of the general population; less than 4% of those participating in the Diabetes and Prevention Trial 1 presented in DKA, and 63.3% were asymptomatic.[117] For children and adolescents with diagnosed diabetes, multidisciplinary and intensive team management approaches have been shown to decrease the frequency of DKA. Unfortunately, obtaining sufficient reimbursement for intensive case management in the United States has been challenging, despite demonstrated savings to the health care system. In a relatively small study, the costs for emergency and hospital visits for those not involved in intervention more than exceeded (125%) the costs of intensive case management.[118] This included only hospital charges and did not include additional costs, such as missed days of work and school, patient and family anxiety, and cognitive and long-term health impact of recurrent DKA and poor glycemic control. In a larger study of home-based psychotherapy for adolescents with poorly controlled diabetes, admissions for DKA were reduced by almost half over a 2-year period, resulting in a cost savings of $23,886 to $72,226 (the range reflecting hospital costs and third-payer costs, respectively).[119] These examples emphasize the need for preventive rather than crisis-based approaches to the pediatric diabetes population.

Very young children with diabetes are the most likely to present in DKA and constitute the age group with the most rapid rise in incidence of diabetes. These data suggest that there are important opportunities for prevention strategies in this age group. Major efforts are needed to address health care disparities overall in children with diabetes, and prevention of DKA is no exception.

CHAPTER 87

Nutrition in the Critically Ill Child

Nilesh M. Mehta

PEARLS

- Provision of individually tailored optimal nutrition to the critically ill child is an important goal of pediatric critical care.
- Malnutrition is prevalent in the pediatric intensive care unit (PICU) and is associated with increased physiologic instability and resource utilization.
- Failure to accurately estimate or measure energy expenditure during critical illness may result in unintended underfeeding or overfeeding. Indirect calorimetry may help prevent energy imbalances.
- The metabolic response to critical illness results in glucose and lipid intolerance and increased protein breakdown. Protein catabolism and nitrogen loss is a characteristic feature of the metabolic stress response to critical illness, resulting in net negative protein balance and loss of lean body mass.
- Failure to deliver optimal energy and protein has been associated with poor outcomes in critically ill adults and children.
- Enteral nutrition (EN) is the preferred mode of nutrient delivery in patients in the PICU with a functioning gastrointestinal tract. Early EN has been associated with positive outcomes in critically ill patients.
- The gastric route is preferred for enteral nutrition. Postpyloric (small bowel) feeding may improve nutrient delivery and may be considered for patients at risk of aspiration or when gastric feeding is not feasible or has not been tolerated.
- Use of EN algorithms and the presence of a dedicated dietitian in the PICU may decrease the barriers to EN and facilitate optimal nutrient delivery.
- Parenteral nutrition is associated with mechanical, infectious, and metabolic complications and should be used in carefully selected patients where EN is contraindicated, not tolerated, or has failed to provide adequate nutrition.

Introduction

Malnutrition is prevalent in critically ill children at the time of admission to the pediatric intensive care unit (PICU).[1,2] Further nutritional deficiencies during their illness course are often incurred due to the burden of illness or suboptimal nutrient intake and may result in poor outcomes. Safe provision of optimal nutrients during hospitalization is an important goal of pediatric critical care. The prediction, estimation, and measurement of true energy expenditure in the PICU patients can be challenging, resulting in unintended underfeeding or overfeeding. Although underfeeding has long been recognized as a problem, a significant proportion of critically ill children are at the risk of being overfed.[3] The enteral route is preferred, and the role and timing of parenteral nutrition continue to be evaluated. However, there exist a myriad of barriers that impede the delivery of prescribed nutrients to the critically ill child and result in a delay or a failure to achieve the prescribed energy and protein goal. Although the complexities of critical care or the nature of illness frequently conflicts with nutrient provision, many perceived barriers to bedside nutrient delivery may be avoidable. Studies have shown significant associations between energy and protein intake during critical illness and outcomes. Future studies will clarify the nature and the role of optimal nutritional therapies in improving patient outcomes in the PICU. Until then, careful screening for malnutrition, awareness of the metabolic state during illness course, accurate assessment of energy demands with attention to energy balance, optimal protein delivery, multidisciplinary efforts to overcome common barriers to nutrient intake at the bedside, and commitment to prioritizing nutritional support during critical illness are desirable.

Malnutrition in the Pediatric Critically Ill Patient

Critical illness increases metabolic demand on the host in the early stages of the stress response when nutrient intake may be limited (see also Chapter 81). As a result, children admitted to the PICU are at risk of deteriorating nutritional status and anthropometric changes with increased morbidity.[1] This effect is more pronounced in a subgroup of patients who are already malnourished or at risk of malnutrition on admission. The prevalence of malnutrition in children admitted to the ICU has remained largely unchanged since the 1990s. One in every four children admitted to the PICU shows signs of acute or chronic malnutrition on admission.[1,2] Malnutrition is associated with increased physiologic instability and the need for increased quantity of care in the ICU.[4] Despite its high prevalence and consequences, medical awareness of malnutrition is lacking. The nutritional status of hospitalized patients is not routinely assessed, and only a minority of patients are referred for expert nutritional consultation or support.[5] Careful nutritional evaluation at admission to the PICU will allow identification of children at risk for further nutritional deterioration and hence candidates for interventions to optimize nutrient intake. Efforts by organizations such as the American Society of Parenteral and Enteral Nutrition (A.S.P.E.N.) have renewed the focus on malnutrition and facilitated a uniform approach toward detecting and managing malnutrition in hospitalized adults and children.[6,7]

Assessment of Nutritional Status

In a proposed concept by A.S.P.E.N., the definition of malnutrition was expanded beyond anthropometric thresholds to include etiology and pathogenesis of malnutrition and its impact on patient outcomes.[7] Uniform use of reference charts and statistics was proposed to compare individual patient measurements to the reference population and thereby classify malnutrition. The association of malnutrition with disease states, in particular inflammation, was highlighted. Assessment of the nutritional status in the critically ill child is vital but often challenging. Clinicians use a combination of anthropometric and laboratory data to diagnose undernourishment. Carefully elicited past history with details of weight gain, dietary history, recent illness, and medications allows identification of risk factors for preoperative malnutrition. Weight on admission to the hospital is important and may be the only measure of the actual dry weight before capillary leak syndrome results in edema and weight gain. Unless regular and accurate weights are obtained, acute changes in nutritional status may be missed or detected late.[8] Children in the PICU are often not weighed as the procedure is deemed to be unsafe or not important. The lack of availability of reliable weight trends in PICU patients reflects the overall low priority among health care workers for nutritional assessment, and as a result the true incidence of malnutrition in this cohort may indeed be underestimated. Physical examination should be directed toward specific signs of nutritional and metabolic deficiencies. Hair, skin, eyes, mouth, and extremities may reveal stigmata of protein-energy malnutrition or vitamin and mineral deficiencies.

A variety of other measurements including arm anthropometry (mid-upper arm circumference and triceps skin fold), body length, and body mass index have been used to monitor growth in children. Recommendations for anthropometric variables and thresholds to classify malnutrition in children are shown in Table 87.1.[9] Although bedside anthropometric methods are inexpensive, they are sporadically applied in hospitalized children, may be insensitive in the setting of critical illness, and are limited by significant interobserver variability. Weight changes and other anthropometric measurements in critically ill children should be interpreted in the context of edema, fluid therapy, volume overload, and diuresis. In the presence of ascites or edema, ongoing loss of lean body mass may not be evident using weight monitoring alone.

TABLE 87.1

Indicators of Pediatric Malnutrition Based on Single Anthropometric Measurements

Primary Indicators	Mild Malnutrition	Moderate Malnutrition	Severe Malnutrition
Weight for height Z score	−1 to −1.9 Z score	−2 to −2.9 Z score	−3 or lower Z score
Body mass index (BMI) for age Z score	−1 to −1.9 Z score	−2 to −2.9 Z score	−3 or lower Z score
Length/height Z score	No data	No data	−3 Z score
Mid-upper arm circumference	−1 to −1.9 Z score	−2 to −2.9 Z score	−3 Z score or lower

Body Composition

Body composition is emerging as a primary determinant of health and a predictor of morbidity and mortality in children. Preservation and accrual of lean body mass during illness are important predictors of clinical outcomes in patients with sepsis,

cystic fibrosis, and malnutrition.[10,11] Body composition is measured by a variety of techniques including body densitometry by underwater weighing, neutron activation analysis, total body potassium determination, bioelectrical impedance assessment (BIA), and dual-energy x-ray absorptiometry (DXA). DXA is a radiographic technique that can determine the composition and density of different body compartments (fat, lean tissue, fat-free mass, and bone mineral content) and their distribution in the body. DXA has been used extensively in pediatric practice for determining fat-free mass, fat mass, and lean mass, and it is recognized as a reference method for body composition research.[12] However, DXA is not practical for application in the PICU. BIA, in contrast, is a bedside technique that can be applied to pediatric patients without exposure to radiation and with ease.[13-15] Electrical current is conducted by body water and is impeded by other body components. BIA estimates the volumes of body compartments, including extracellular water and total body water (TBW). TBW measures can be used to estimate lean body mass by applying age-appropriate hydration factors. BIA has not been validated in critically ill populations; hence, its use outside clinical studies is not recommended in the PICU. The ideal bedside body composition measurement technique in critically ill patients remains elusive.

Biochemical Assessment

The nutritional status can also be assessed by measuring the visceral (or constitutive) protein pool, the acute-phase protein pool, nitrogen balance, and resting energy expenditure. Visceral proteins are rapid turnover proteins produced in the liver. Low circulating levels of visceral protein are seen in the setting of malnutrition, inflammatory states, and impaired hepatic synthetic function. The reliability of serum albumin as a marker of visceral protein status is questionable. Albumin has a large pool and a half-life of 14 to 20 days, and it is not an indicator of the immediate nutritional status. Serum albumin may be affected by changes in fluid status, albumin infusion, sepsis, trauma, and liver disease, and these changes are independent of nutritional status. Prealbumin (also known as transthyretin or thyroxine-binding prealbumin) is a stable circulating glycoprotein synthesized in the liver. It binds with retinol-binding protein and is involved in the transport of thyroxine and retinol. Prealbumin, so named because of its proximity to albumin on an electrophoretic strip, is readily measured in most hospitals and is a good marker for the visceral protein pool.[16,17] It has a half-life of 24 to 48 hours and reflects more acute nutritional changes. Prealbumin concentration is diminished in liver disease. Acute-phase reactant proteins are elevated proportional to the severity of injury in response to cytokines released during stress response and have been be used to longitudinally monitor the inflammatory response. Serum levels of acute-phase protein are elevated in children within 12 to 24 hours after burn injury due to hepatic reprioritization of protein synthesis.[18] When measured serially, serum prealbumin and C-reactive protein (CRP) are inversely related (ie, serum prealbumin levels decrease and CRP levels increase with the magnitude proportional to injury severity and then return to normal as the acute injury response resolves). In infants after surgery, decreases in serum CRP values to less than 2 mg/dL have been associated with the return of anabolic metabolism and are followed by increases in serum prealbumin levels.[19] Proinflammatory cytokines such as interleukin 6 (IL-6) are

recognized as early markers of the systemic inflammatory response syndrome (SIRS) in several disease models. Serum concentrations of IL-6 may be useful in identifying patients at risk for nutritional deterioration and to determine whether the inflammatory response is intact. Chemistry profiles should be monitored on admission and repeated periodically. Serum electrolytes, blood urea nitrogen, glucose, coagulation profile, iron, magnesium, calcium, and phosphate levels are routinely monitored. Adequacy of cellular immunity can be estimated through the measurement of total lymphocyte count and by delayed-type hypersensitivity testing with a series of common antigens (eg, candida, Trichophyton, tuberculin).

Metabolic Consequences of Critical Illness

The energy burden imposed by the metabolic response to injury, surgery, or inflammation may be proportional to the severity and duration of the stress but cannot always be accurately estimated and varies in intensity and duration between individuals. Importantly, nutritional support itself cannot reverse or prevent the metabolic stress response but rather offsets the catabolic losses during this state. Failure to provide optimal calories and protein during the acute stage of illness can exaggerate existing nutritional deficiencies or further exacerbate underlying nutritional status. Respiratory compromise involving loss of respiratory muscle mass, cardiac dysfunction and arrhythmias involving loss of myocardial muscle tissue, and intestinal dysfunction involving loss of the gut barrier contribute to the morbidity and mortality of critical illness. In some cases, overestimation of this energy cost of metabolic stress may result in provision of energy in excess of requirement. Hence, large energy imbalances attributable to underfeeding and overfeeding in critically ill children must be avoided.[3] This can be prevented by individualized nutritional regimens that are tailored for each child and reviewed regularly during the course of illness. In a trial of a 12-week individualized nutritional intervention in home-ventilated children, significant improvements were observed in respiratory and body composition variables.[20] A basic understanding of the metabolic events that accompany critical illness and surgery is essential for planning appropriate nutritional support in critically ill children.

The unique hormonal and cytokine profile manifested during critical illness is characterized by an elevation in serum levels of insulin, glucagon, cortisol, catecholamines, and proinflammatory cytokines.[21] Increased serum counterregulatory hormone concentrations induce insulin and growth hormone resistance, resulting in the catabolism of endogenous stores of protein, carbohydrate, and fat to provide essential substrate intermediates and energy necessary to support maintenance energy and micronutrient needs in addition to the ongoing metabolic stress response. Fig. 87.1 illustrates the basic pathways involved in the metabolic stress response. In general, the net increase in muscle protein degradation, characteristic of the metabolic stress response, results in a large number of free amino acids in the circulation. Free amino acids are used as the building blocks for the rapid synthesis of proteins that act as inflammatory response mediators and are used for tissue repair. Protein breakdown may continue for an extended period of time, in an attempt to channel the amino acids through the liver, wherein their carbon skeletons are used to create glucose through gluconeogenesis and for production of glucose as the preferred energy substrate for the brain, erythrocytes,

and renal medulla. Reprioritization of protein during the metabolic stress increases the synthesis of acute-phase reactant proteins such as C-reactive protein, alpha$_1$-acid glycoprotein, haptoglobin, alpha$_1$-antitrypsin, alpha$_2$-macroglobulin, ceruloplasmin, and fibrinogen. Plasma concentrations of other proteins, including transferrin and albumin, decrease with injury or sepsis. Overall, the intense protein catabolism during critical illness outstrips anabolism with net negative protein balance. This condition results in weight reduction and rapid loss of lean body mass. The intense catabolism seen in metabolic stress cannot be suppressed by supplying calories, and negative protein balance continues relentlessly. This is one of the principal differences between stress response and starvation.

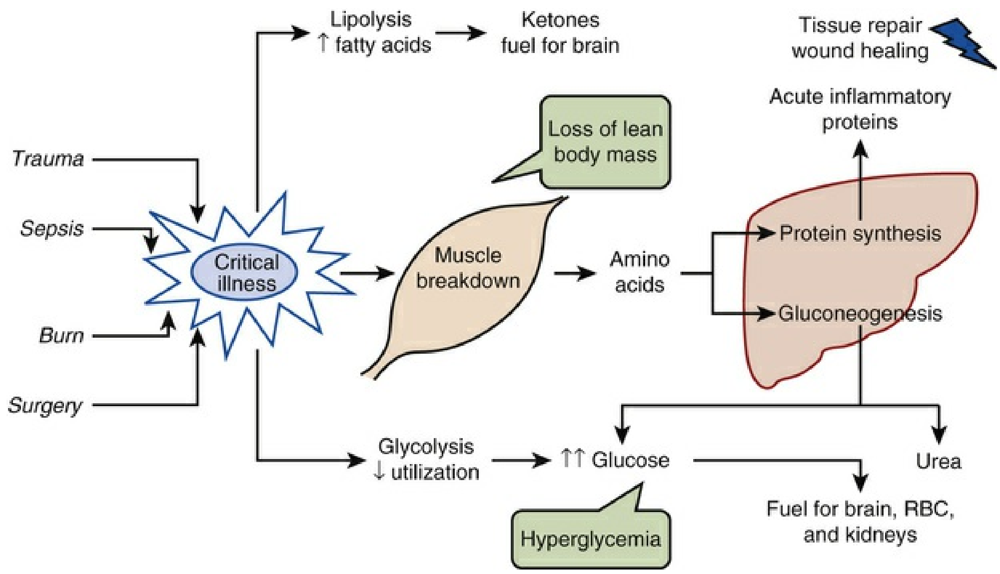

FIG. 87.1 The metabolic response to stress. (Reproduced with permission from Mehta N, Jaksic T. The critically ill child. In: Duggan C, Watkins JB, Walker WA, eds. Nutrition in Pediatrics. 4th ed. Hamilton, Ontario, Canada: BC Decker; 2008:663-673.)

Starvation, or protein-calorie malnutrition, may be caused by socioeconomic, psychosocial, disease-related, or iatrogenic factors. The metabolic response to starvation involves decreased secretion of insulin and thyroid hormones, normal secretion of glucocorticoids and catecholamines, and decreased oxygen consumption. In starvation states, the body tries to preserve itself by using less energy for basic metabolic functions; thus, overall metabolic rate decreases. Metabolism shifts to use fat as a primary energy source, and the corresponding ketones help provide fuel for the brain and spare glucose and protein utilization. However, body tissues still must be broken down to supply amino acids for other critical functions, eventually leading to a loss of lean body mass, vital organ wasting, and possibly death. Table 87.2 summarizes the basic differences between starvation and metabolic stress.

TABLE 87.2
Metabolic Stress Versus Starvation

	Metabolic Stress	Starvation

BMR	⇑⇑	⇔⇓
Oxygen consumption (VO_2)	⇑⇑	⇓
Protein catabolism	⇑⇑⇑	⇔
UUN	⇑⇑	⇔
Weight loss	Rapid	Slow
LBM loss	Early	Late
Response to caloric intake	Protein catabolism continues	Protein catabolism halted
Insulin, cortisol, and catecholamines	⇑⇑	⇓
Ketones	⇑⇑	⇔
Gluconeogenesis	⇑	⇓

BMR, basal metabolic rate; *LBM*, lean body mass; *UUN*, urinary urea nitrogen.

Carbohydrate turnover is simultaneously increased during the metabolic stress response, with a significant increase in glucose oxidation and gluconeogenesis. The administration of exogenous glucose does not blunt the elevated rates of gluconeogenesis, however, and net protein catabolism continues unabated.[22] A combination of dietary glucose and protein may improve protein balance during critical illness, primarily by enhancing protein synthesis. The stress response to injury stimulates lipolysis and increased rates of fatty acid oxidation.[23] Increased fat oxidation reflects the premier role of fatty acids as an energy source during critical illness. Triglycerides in adipose tissue are then cleaved by hormone-sensitive lipase into fatty acids and glycerol. Fatty acids are oxidized in the liver for energy via the tricarboxylic acid cycle. As seen with the other catabolic changes associated with the stress response, the provision of dietary glucose does not decrease fatty acid turnover in times of illness. The increased demand for lipid use in the setting of limited lipid stores puts the metabolically stressed neonate or previously malnourished child at high risk for the development of essential fatty acid deficiency.[24,25] Preterm infants are most at risk for developing essential fatty acid deficiency after a short period of a fat-free nutritional regimen.[25,26] Nutritional therapy should support the metabolic changes occurring during the acute catabolic stage. With resolution of a hypermetabolic stress response, an anabolic phase typically follows, with increased release of growth hormone (GH) and insulin-like growth factor-1 (IGF-1). Supply of adequate nutrition is essential for this recovery phase. In summary, the metabolic response to critical illness results in glucose and lipid intolerance and increased protein breakdown.

Underfeeding and Overfeeding in the Pediatric Intensive Care Unit

Individual assessment of energy requirements and provision of optimal energy should be the standard of care in the PICU. Both underfeeding and overfeeding are prevalent in the PICU, with resultant nutritional deficiencies that are associated with complications.[4,27] True energy expenditure during acute illness may not be easily predicted, and several studies have documented discrepancies in measured versus equation-estimated energy expenditure.[28-30] Unless increased energy requirements during the acute stage of illnesses are accurately measured and matched by adequate intake, cumulative energy deficits will ensue with a decrease in weight, loss of critical lean body mass, and worsening of existing malnutrition. A variety of barriers, both unavoidable as well as some avoidable, exist that impede optimal nutrient delivery at the bedside and contribute to the likelihood of underfeeding in

the PICU.[31,32] Underfeeding during acute illness with cumulative negative energy balance has been associated with poor outcomes in critically ill adults.[33] In a large multicenter cohort study, delivery of a higher percentage of the prescribed energy goal was associated with significantly lower 60-day mortality.[34] On average, percentage daily nutritional intake (enteral route) compared to the prescribed goals in this study was 38% for energy and 43% for protein (Fig. 87.2).

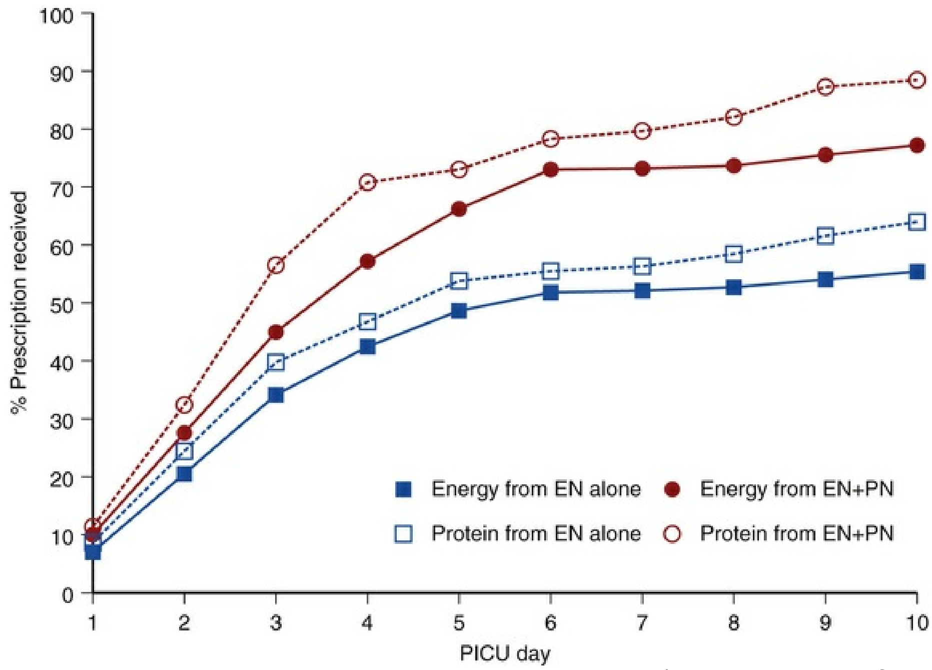

FIG. 87.2 Daily mean cumulative energy intake (as percentage of prescribed goal) for the cohort. *EN*, enteral nutrition; *PN*, parenteral nutrition; *PICU*, pediatric intensive care unit.

On the other hand, overfeeding in the PICU is prevalent but may be underrecognized and have a potential negative impact on patient outcomes. Children do not predictably mount the characteristic hypermetabolic stress response as is seen in adults. The metabolic response to stress from injury, surgery, or illness is variable, and the degree of hypermetabolism is unpredictable and unlikely to be sustained during a prolonged course in the PICU.[35] Critically ill children cannot be presumed to be hypermetabolic following acute illness or injury, and energy expenditure may actually be decreased in some groups of patients.[36-39] Children on extracorporeal life support or after surgery have failed to show any significant hypermetabolism, and measured energy expenditure is close to resting energy expenditure in these populations.[40] Critically ill children who are sedated and mechanically ventilated may have a significant reduction in actual total energy expenditure, due to multiple factors. Stress or activity correction factors factored into basal energy requirement estimates, in an attempt to account for the perceived hypermetabolic effects of the illness, may result in overfeeding in hypometabolic patients.[41,42] Overfeeding may have deleterious consequences for the critically ill child.[27,43] Overfeeding critically ill children is associated with net lipogenesis, hepatic steatosis, liver dysfunction, and increased CO_2 production and difficulty in ventilator weaning.[44] Investigators have proposed hypocaloric diets in critically ill

adults.[45,46] Hypocaloric diets may have a protein-sparing effect and have demonstrable benefits in critically ill obese patients. However, it is uncertain if administration of energy intake lower than the measured expenditure is appropriate for the critically ill pediatric patient. There is not enough evidence to recommend its general use in critically ill children. In general, the energy goals in critically ill children should be individualized and based on accurate and serial assessment of energy requirement during the illness course.

Current recommendations for nutritional requirements of the critically ill child are derived from limited data, based on studies in healthy children and based on limited methodological approaches. Table 87.3 summarizes the recommended energy and protein intake for critically ill children. The components of total energy expenditure in children include (1) basal metabolic rate (BMR) 70%, (2) diet-induced thermogenesis (DIT) 10%, (3) energy expended during physical activity (PA) 20%, and (4) energy expended for growth. The sum of these components determines the energy requirement for an individual. These traditional components of energy expenditure in healthy children may not apply during critical illness (Table 87.4). Thus prescribing optimal energy for the critically ill child requires careful review of each component of total energy expenditure. Recommendations for energy requirements were based on estimates of basal metabolic rate or resting energy expenditure (REE) derived by either indirect calorimetry or standard equations.[37,47] REE estimates have a large individual variability, and predictive equations are unreliable, particularly in underweight, overweight, or critically ill children.[30,48,49] Newer equations have attempted to improve the prediction of REE in children by accounting for weight-based groups or including pubertal staging, with variable success.[49,50] These equations have not satisfactorily been validated in critically ill children.[51] The variability of the metabolic state may be responsible for the failure of estimation equations in accurately predicting the measured REE in critically ill children. The A.S.P.E.N. guidelines recommend indirect calorimetry when available for the most accurate assessment of energy expenditure in critically ill children.[52]

TABLE 87.3

Recommended Energy and Protein Allowances During Critical Illness

	Age (years)	Energy (kcal/kg/day)	Protein (g/kg/day)
Infants	0-0.5	115	2.2
	0.5-1	105	2.0
Children	1-3	100	1.8
	4-6	85	1.5
	7-10	86	1.2
Males	11-14	60	1.0
	15-18	42	0.8
Females	11-14	48	1.0
	15-18	38	0.8

TABLE 87.4

Components of Energy Expenditure: Normal Health versus Critical Illness

Component	Normal Health	Critical Illness
BMR	Energy needed for maintaining vital processes of the	Related to metabolic state. May be increased

(60%-70%)	body. It is measured in a recumbent position, in a thermoneutral environment after 12 to 18 hours fast, just when the individual has awakened before starting daily activities. Not practical for bedside Sleeping energy expenditure, a component of BMR, was shown to be equal to REE 3 0.9 Corresponds to lean body mass.	in conditions such as inflammation, fever, acute or chronic disease (ie, cardiac, pulmonary). Related to lean body mass.
REE (50%-60%)	BMR + 10% Usually measured instead of BMR. REE is measured at rest in a thermoneutral environment, after 8-12 hours fast and not immediately after awakening.	Measured by indirect calorimetry with steady-state conditions.
DIT or TEF (10%)	Reflects the amount of energy needed for food digestion, absorption, and part of synthesis.	Increased energy needs following enteral feeding return to baseline approximately >4 hrs of feeding.
Growth (variable)	Energy for growth may be higher in healthy infants <2 years and during catch-up growth.	Probably halted?
Physical activity (PA) (variable)	Depends on age, activity level. Decreased in hospitalized patients.	Sedation, muscle relaxants, decreased activity.
Stress	—	Variable. Probably overestimated during critical illness.
Total energy expenditure	REE + DIT + PA + Growth	Probably close to REE in most critically ill children. Addition of stress factors may be necessary where relevant.

BMR, basal metabolic rate; *DIT*, diet-induced thermogenesis; *REE*, resting energy expenditure; *TEF*, thermic effect of food.

Indirect Calorimetry

Historically, indirect calorimetry (IC) has been regarded as the gold standard for accurate measurement of REE. Energy expenditure is obtained by measuring the volume of oxygen consumed (VO_2) and the volume of CO_2 produced (VCO_2) over a period of time.[53] VO_2 and VCO_2 values are used to calculate REE using the modified Weir equation: $REE = [VO_2\ (3.941) + VCO_2\ (1.11)] \times 1440$. This technique has been validated in healthy children by using a whole-body chamber to allow 24-hour measurement. For obvious reasons, the whole-body chamber cannot be used in critically ill children. The application of IC in different PICU populations has shown the variability in energy expended during illness. In the past, studies have demonstrated a relatively higher resting metabolic rate in critically ill children (37% higher than the resting metabolic rate of age-matched healthy controls).[54] However, contrary to beliefs held for years, studies have shown that the total energy expenditure is not increased in head-injured children, postoperative general surgical patients, or children after major cardiac surgery.[55-57] The muted metabolic responses to major surgeries and injuries in studies may reflect advances in surgical and intensive care over the years. In critically ill mechanically ventilated children, use of sedation and muscle paralysis decreases the component of energy requirement related to physical activity,[44] and caloric needs in the critically ill child may be lower than previously considered. IC remains sporadically applied in critically ill children despite mounting evidence of the inaccuracy of estimated basal metabolic rate using standard equations. This could potentially subject a subgroup of children in the PICU to the risk of underfeeding or overfeeding. However, IC application is not feasible in all patients due to (1) specific subject requirements, (2) device limitations,

and (3) the need for expertise and resources. Table 87.5 describes some of the common problems associated with IC testing in critically ill children. In the era of resource constraints, IC may be applied or targeted for certain high-risk groups in the PICU.[3] Selective application of IC may allow many units to balance the need for accurate REE measurement and limited resources (see Table 87.6 for suggested criteria for targeted IC).[52] Although IC application has illuminated our understanding of energy expended during critical illness, this is yet to be translated into improving patient outcomes. Studies examining the role of simplified IC technique, its role in optimizing nutrient intake, its ability to prevent overfeeding or underfeeding in selected subjects, and the cost-benefit analyses of its application in the PICU are desirable. The effect of energy intake on outcomes needs to be examined in pediatric populations, especially in those on the extremes of body mass index (BMI).

TABLE 87.5

Factors Associated With Inaccurate or Unreliable Indirect Calorimetry Measurements

Error in VCO_2 Measurement	Limitations or Mechanical Issues With the Device	Failure to Reach Steady State
Air leak >10% around endotracheal tube	High inspired Fio2 (>60%)	Recent interventions (suctioning, painful procedure)
Air leak in the circuit	Calibration issues	Fever, seizures, dysautonomia
Chest tube for pneumothorax	Moisture or obstruction due to water in the circuit	Recent change in ventilator settings
		Study period too short

TABLE 87.6

Suggested Criteria for Targeted Indirect Calorimetry[3,52]

Children at High Risk for Metabolic Alterations Who Are Suggested Candidates for Targeted Measurement of Resting Energy Expenditure (REE) in the PICU Include the Following:
• Underweight (body mass index [BMI] <5th percentile for age), at risk of overweight (BMI >85th percentile for age) or overweight (BMI >95th percentile for age) • Children with >10% weight gain or loss during ICU stay • Failure to consistently meet prescribed caloric goals • Failure to wean, or need to escalate respiratory support • Need for muscle relaxants for >7 days • Neurologic trauma (traumatic, hypoxic, or ischemic) with evidence of dysautonomia • Oncologic diagnoses (including children with stem cell or bone marrow transplant) • Children with thermal injury • Children requiring mechanical ventilator support for >7 days • Children suspected to be severely hypermetabolic (status epilepticus, hyperthermia, systemic inflammatory response syndrome, dysautonomic storms, etc.) or hypometabolic (hypothermia, hypothyroidism, pentobarbital or midazolam coma, etc.) • Any patient with ICU LOS >4 weeks may benefit from indirect calorimetry to assess adequacy of nutrient intake.

LOS, length of stay; *PICU*, pediatric intensive care unit.

Another method of energy expenditure determination is based on the use of doubly labeled water. However, at this time the technique remains confined to research settings. Stable isotope technique has been available for many years and was first applied for energy expenditure measurement in humans by Schoeller and van Santen[58] in 1982. Isotope studies using doubly labeled water have since been validated and following intense and skeptical scrutiny have now been established as a gold standard for total energy expenditure estimation with widespread

application.[43,59-62] In this method, stable isotopes of water (^2H_2O and $H_2{}^{18}O$) are administered enterally. They mix with the body water and the ^{18}O is lost from the body as both water and CO_2, whereas the ^2H is lost from the body only as water. The difference in the rates of loss of the isotopes ^{18}O and ^2H from the body reflects the rate of CO_2 production, which can be used to calculate the total energy expenditure. This method has advantages in children because of its noninvasive nature. However, isotope decay is measured over two half-lives of the isotope, and hence the technique only gives an average estimate of total energy expenditure over a period of a few days. Analytic errors in the mass spectrometric estimation of isotope enrichment, isotope fractionation during CO_2 formation or vaporization of water, and the calculation of total body water or respiratory quotient are factors that might introduce errors in the estimation of total energy expenditure with this technique. If the necessary conditions are met, the doubly labeled water technique is currently the best method for estimating energy expenditure because expired gas analysis is not required, and serial measurements of stable isotopes in urine samples provide an objective assessment of energy expenditure over a period of 4 to 21 days. However, the doubly labeled water technique for determining energy expenditure is difficult to use in critically ill children because it requires fluid balance in the steady state. This is a major problem in the critically ill child with active capillary "leak" syndrome. Hence, decreased urinary output, capillary leak syndrome, use of diuretics, and fluid overload exclude the use of this technique. The isotope costs and availability may be concerns, and the doubly labeled water technique cannot measure brief periods of peak energy expenditure.

In summary, energy expenditure must be carefully evaluated throughout the course of critical illness, using actual measurements when available. In patients meeting the requirements for this test, IC provides an accurate measurement of REE. IC may need to be targeted to specific patient groups due to the risk of metabolic instability, but it may help prevent unintended underfeeding and overfeeding in these patients. In the absence of measured REE, equation estimated REE may be used. However, the uniform application of stress factors is not advisable and must only be used in individual cases after careful evaluation. Once energy needs are determined, the optimal substrate required for maintenance of energy needs is mixed fuel (glucose and fat). The proportion of each varies according to the clinical situation.

Protein Requirements

Protein turnover and catabolism are increased several-fold in critically ill children. This is one of the most characteristic features of the metabolic stress response and probably represents an adaptive response that was critical to survival of human prehistoric ancestors as a race. An advantage of high-protein turnover is that a continuous flow of amino acids is available for synthesis of new proteins. Specifically, this process involves a redistribution of amino acids from skeletal muscle to the liver, wound, and other tissues involved in the inflammatory response. This allows for maximal physiologic adaptability at times of injury or illness. The catabolism of muscle protein to generate glucose and inflammatory response proteins is an excellent short-term adaptation, but it is ultimately limited in children

and neonates because of the limited protein reserves available. Children, especially preterm infants, have reduced macronutrient reserves with less than half the protein content of adults.[63] Although children with critical illness have increases in both whole-body protein degradation and whole-body protein synthesis, it is the former that predominates during the stress response and results in a net negative protein balance. Infants and malnourished children with already decreased or depleted lean body mass reserves may not tolerate the ill effects of cumulative negative protein balance. In a large international cohort study of more than 1200 mechanically ventilated children, 60-day mortality was lower in children who received a higher proportion of their daily prescribed protein goal.[64] Fig. 87.3 depicts the linear relation between enteral protein intake adequacy (percentage of the protein goal delivered) and 60-day mortality in mechanically ventilated patients in this cohort. A similar association between lower protein intake and mortality was also shown in a large international study of adult critically ill patients.[45] These reports suggest a strong association between protein intake and outcomes, which is both biologically plausible and independent of energy intake.

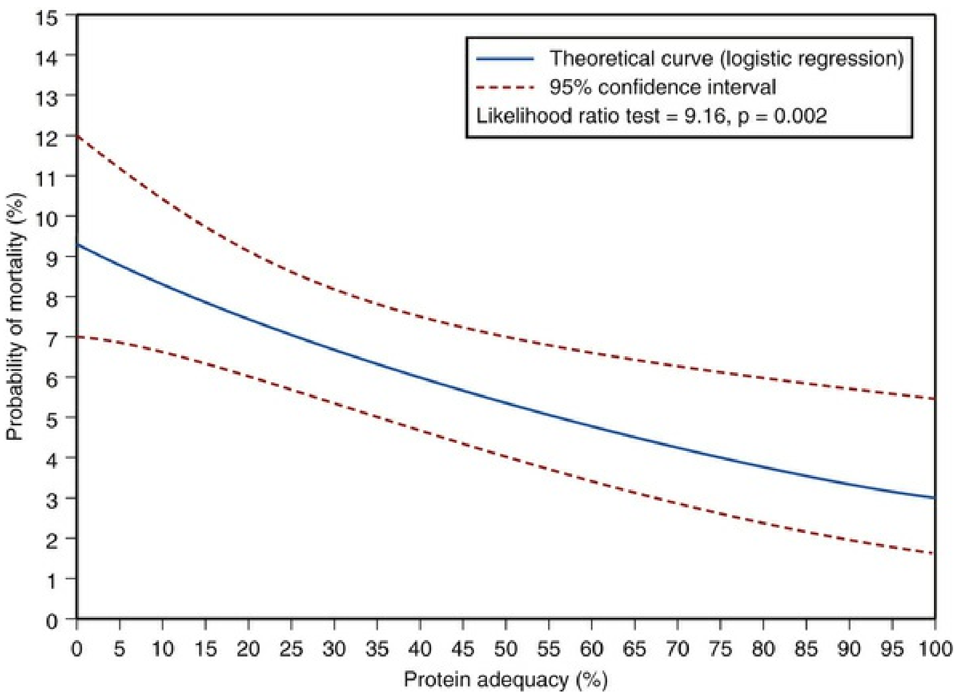

FIG. 87.3 Linear relation between enteral protein intake adequacy (percentage of the protein goal delivered) as a continuous variable and 60-d mortality. (With permission from Mehta NM, et al. Adequate enteral protein intake is inversely associated with 60-d mortality in critically ill children: a multicenter, prospective, cohort study. Am J Clin Nutr. 2015;102:199-206.)

Unlike starvation, the provision of dietary carbohydrate alone is ineffective in reducing the protein catabolism or endogenous glucose production via gluconeogenesis in the metabolically stressed state.[22] Therefore, without elimination of the inciting stress for catabolism (ie, the critical illness or injury), the progressive breakdown of muscle mass from critical organs may result in loss of diaphragmatic and intercostal muscle (leading to respiratory compromise) and the loss of cardiac

muscle.[65,66] The amount of protein required to optimally enhance protein accretion is higher in critically ill than in healthy children. Infants demonstrate 25% higher protein degradation after surgery and a 100% increase in urinary nitrogen excretion with bacterial sepsis.[65,66] Following burn injury, protein catabolism and whole body protein turnover are increased and may persist for up to several months after the inciting event.[67] The provision of dietary protein sufficient to optimize protein synthesis, facilitate wound healing and the inflammatory response, and preserve skeletal muscle protein mass is the most important nutrition intervention in critically ill children. Supply of adequate proteins and energy intake improves protein balance by increasing protein synthesis, although protein breakdown is not affected. The amount of protein required to maintain a positive nitrogen balance may vary according to the severity of illness. Nitrogen balance is used as a surrogate for protein balance. In a systematic review of protein supplementation trials, a minimum of 1.5 g/kg/day protein intake was required to achieve a positive nitrogen balance.[68] This threshold of 1.5 g/kg/day protein intake was again shown to be the minimum required to achieve a positive protein balance in studies of critically ill children.[69,70] Despite these studies, the current prescription for protein in the PICU remains low. It is clear that the requirements of protein in a critically ill child exceed those for a healthy child. The dietary reference intake (DRI) recommendations for protein intake for healthy children are inadequate to meet the demands in critically ill children and should not be used to guide protein prescription in the PICU population.[64] Failure to deliver the prescribed protein due a variety of barriers at the bedside further increases the gap between requirement and actual delivery. Further studies to determine the individual requirement of specific amino acids under catabolic conditions are necessary, particularly in view of the important functions of amino acids, not only in protein synthesis but as signaling molecules[71] and precursors for important substrates such as glutathione[46] and methyl group donors.[72] Alternatively, excessive protein administration could be deleterious, particularly in children with marginal hepatic or renal function. Neonates with higher protein intakes have been shown to develop azotemia, pyrexia, and possible long-term detrimental effects on cognitive development.[73,74] Hence, future studies on specific nutritional and functional requirements of amino acids and their impact on functional outcomes are needed.

Lipid Requirements

Nonprotein calories are commonly provided as carbohydrates (55% to 65%) and fat (35% to 45%). In the absence of adequate lipid supplementation in the diet, critically ill children, who have depleted lipid stores at baseline, are likely to suffer essential fatty acid deficiency.[72] Lipid administration is generally restricted to 30% to 40% of the total calories, and after an initial prescription of 1 g/kg/day it may be gradually increased to 2 to 4 g/kg/day, depending on the tolerance level. Triglyceride levels should be regularly monitored for lipid tolerance. Concentrated lipid formulas (Intralipid 20%) should be used, given the limitation on fluid volume for administration of nutritional support. The potential role for omega-2 fatty acids during critical illness is discussed further in the parenteral nutrition section.

Micronutrient Requirements

Micronutrients play significant physiologic roles. Beneficial effects of micronutrients such as fat-soluble vitamins (A, D, E, and K), water-soluble vitamin (C), zinc, selenium, and folic acid have been described in selected groups of patients in well-defined settings. Presumed safety of micronutrients and probably exaggerated efficacy and generalized applicability to heterogeneous populations are factors that may be responsible for the widespread prescription of these compounds.[75] Commercially available antioxidant nutrients need to be scrutinized for optimal dosage and side effects in the clinical setting where they are most likely to be beneficial. Hospitalized patients, especially those with critical illness, currently receive these additives in accordance with Food and Nutrition Board recommendations for daily allowances. The antioxidant properties of certain micronutrients have renewed interest in their role during critical illness.[76] Vitamins C and E have important antioxidant properties. Selenium has also been shown to be a critical micronutrient with antioxidant functions in patients with thermal injury and trauma.[77] A complex system of special enzymes, their cofactors (selenium, zinc, iron, and manganese), sulfhydryl group donors (glutathione), and vitamins (E and C) form a defense system to counter the oxidant stress seen in the acute phase of injury or illness. Critically ill patients may have variable deficiencies of micronutrients in the early phase of illness. Vitamins and trace elements are redistributed from central circulation to tissues and organs during systemic inflammatory response syndrome (SIRS).[76] Levels of trace elements, such as iron, selenium, and zinc, and water-soluble vitamins are decreased, whereas copper and manganese levels may be increased.[78] In addition, trauma and thermal injuries are characterized by extensive losses of biological fluids through wound exudates, drains, and hemorrhage, which cause negative micronutrient balances. The reduced stores of these enzyme cofactors, vitamins, and trace elements decrease rapidly after injury and remain at subnormal levels for weeks. Low endogenous stores of antioxidants are associated with an increase in free radical generation, augmented systemic inflammatory response, cell injury, and increased morbidity and mortality in the critically ill.[59,60]

Preliminary studies have shown low plasma zinc levels in critically ill children, associated with inflammatory markers and degree of organ failure.[61,62] These observations have driven dosing studies to examine the efficacy of zinc supplementation in critically ill children.[58] There has been increased interest in the role of vitamin D as an antioxidant. Serum levels of vitamin D are decreased in children with severe burns.[79] Vitamin D status may be compromised for months after burn injury. Indeed studies show a much larger incidence of vitamin D deficiency in the general population.[80-84] Significantly low levels of vitamin D have been reported in critically ill children.[85,86] In a study of more than 500 critically ill children, the median 25(OH)D level was 22.5 ng/mL and over 40% of the cohort was deficient (level <20 ng/mL).[86] In another prospective multicenter observational study of critically ill children from Canada, low levels of vitamin D were independently associated with severity of illness, catecholamine utilization, need for fluid boluses, and PICU length of stay.[87] The concept of early micronutrient supplementation to prevent the development of acute deficiency, to rectify the oxidant-antioxidant balance, and to reduce oxidative-mediated injuries to organs has driven trials in

critically ill patients.[88] Antioxidant research in the critically ill has focused on copper, selenium, zinc, vitamins C and E, and the vitamin B group. Most of these studies were performed in relatively small patient populations presenting with heterogeneous diseases, such as trauma, burns, sepsis, or acute respiratory distress syndrome, however, and thus are underpowered to detect a treatment effect on clinically important outcomes. Based on a systematic review of trials, supplementing critically ill patients with antioxidants, trace elements, and vitamins was deemed safe and associated with a reduction in mortality in critically ill patients.[76] However, a trial of glutamine and antioxidant supplementation in critically ill adults did not show any benefit from antioxidant supplementation for the primary outcome, 28-day mortality, or any of the secondary outcomes.[89]

Electrolyte management in critically ill children can be complicated because of existing deficiencies, fluid shifts, increased insensible losses, drainage of bodily secretions, and renal failure (see also Chapter 73). Intravenous fluids or parenteral nutrition (PN) prescriptions need to be reviewed daily in light of the basic electrolytes and blood sugar levels. In children with significant gastrointestinal fluid loss (gastric, pancreatic, small intestinal, or bile), the actual measurement of electrolytes from the drained fluid may assist in prescribing replacement fluids. Acute changes in serum electrolytes that require urgent electrolyte replacement must not be managed by changes in the PN infusion rate or composition, because this method may be imprecise and potentially dangerous. Phosphate and magnesium levels are often abnormal in critically ill children, especially in those with existing nutritional deficiencies, sepsis, or ongoing nutritional deprivation.

Refeeding Syndrome

Aggressive nutritional rehabilitation in malnourished patients or those with prolonged fasting results in a constellation of biochemical and clinical features with cardiopulmonary complications. This well-described entity is called refeeding syndrome and is often unrecognized. Hypophosphatemia is the hallmark of refeeding syndrome, which is also associated with hypomagnesemia, hypokalemia, and fluid retention. Patients admitted to the PICU with nutritional deficiencies, those with chronic conditions causing malnutrition, or those fasted for 10 to 14 days are at risk of refeeding syndrome following aggressive oral, enteral, or parenteral nourishment. The introduction of nutrition in these patients stimulates anabolism, with a switch from protein and fat catabolism to predominantly carbohydrate metabolism. Glucose becomes the primary energy source leading to insulin release. Insulin-mediated cellular uptake of glucose causes an intracellular shift of phosphate, potassium, and magnesium, thus rapidly lowering their serum levels. Insulin also causes sodium and fluid retention with rapid expansion of extracellular fluid volume. The clinical manifestations of refeeding syndrome are a result of the dyselectrolytemia and fluid overload involving the cardiorespiratory, neuromuscular, and hematologic complications. Hypotension, respiratory failure, muscular weakness, confusion, seizures, coma, and even death may result from refeeding syndrome.

Awareness of this syndrome, identification of at-risk patients, and gradual introduction of nutrition in these individuals help prevent the refeeding syndrome. Calories may be introduced at 25% to 50% of requirement and increased 10% to 25%

daily until the caloric goal is met. Careful monitoring of electrolytes and vigilance for clinical manifestations of the syndrome allow early detection of complications, and feeds are advanced in the setting of biochemical stability. Prompt correction of electrolyte abnormalities, close attention to fluid balance, and supplementation with multivitamins will help avoid the cardiorespiratory sequelae from refeeding in the critically ill child.

Enteral Nutrition in Critically Ill Children

Enteral nutrition (EN) is the preferred mode of nutrient intake in critically ill patients with a functional gastrointestinal system due to its lower cost and complication rate when compared to PN.[52] Early institution of EN is associated with beneficial outcomes in animal models and human studies[76] and has been increasingly implemented during critical illness, often using nutrition guidelines or protocols.[90] Early enteral nutrition has been shown to decrease infectious episodes and decrease length of hospital stay in critically ill patients.[91] In a multicenter retrospective study including 12 PICUs, early EN was associated with lower odds of mortality.[92] Early EN, defined as delivery of at least 25% of energy goal in the first 48 hours after admission, was achieved in 27% of the 5105 patients in this study. Centers have achieved successful implementation of early enteral nutrition using institutional protocols.[90,93]

Although early EN has been adopted in a majority of the units, subsequent maintenance of enteral nutrient delivery remains elusive, as EN is frequently interrupted in the intensive care setting for a variety of reasons, some of which are avoidable.[32,94] Frequent interruptions in enteral nutrient delivery may affect clinical outcomes secondary to suboptimal provision of calories and reliance on PN. This author has reported EN interruptions in a third of patients in the PICU who were started on EN.[31] EN was frequently interrupted for avoidable reasons. Patients experiencing avoidable EN interruptions had more than a threefold increase in the use of PN and significant delay in reaching caloric goals. This collaborative study, examining bedside nutrition practice, illustrates some of the challenges to the provision of nutrition support and highlights opportunities for practice modification. Fasting for procedures and intolerance to EN were the most common reasons for prolonged EN interruptions. Interventions aimed at optimizing EN delivery must be designed after examining existing barriers to EN and directed at high-risk individuals who are most likely to benefit from these interventions. Knowledge of existing barriers to EN, such as those identified in this study, will allow appropriate interventions to be planned. Intolerance to enteral feeds may be a limiting factor, and supplementation with PN in this group of patients allows earlier optimal nutritional intake. Taylor and colleagues reviewed nutritional delivery in a group of 95 children in a PICU over a 12-month period and made similar observations.[95] Children received a median of 58.8% (range 0% to 277%) of their estimated energy requirements in this review. Enteral feeding was interrupted on 264 occasions to allow clinical procedures. Rogers and colleagues reviewed nutritional intake in 42 patients admitted to an Australian tertiary-level PICU over 458 ICU days.[32] When actual energy intake was compared with estimated energy requirement, only 50% of patients had received full estimated energy requirements after a median of 7 days in the ICU. Fluid restriction is a major factor hindering the

achievement of estimated energy requirements despite maximizing the energy content of feeds. Table 87.7 summarizes some of the barriers to successful enteral feeding in the PICU.

TABLE 87.7

Barriers to Enteral Nutrient Delivery in the Pediatric Intensive Care Unit

Fasting before procedures
Endotracheal tube–related procedures (intubation, extubation)
Major operative procedures
Other procedures requiring general anesthesia
Bedside procedures requiring sedation
Radiology suite or interventional radiology procedures
Fluid restriction
Delay in establishing enteric tube for feeding
Delay or difficulty in enteric tube placement
Malpositioned, obstructed, or displaced enteric tube
Gastrointestinal dysfunction
Malabsorption, diarrhea, or severe constipation
Ileus associated with opioid use or postoperative
Patients at risk of aspiration of gastric contents
Holding EN for perceived intolerance
High gastric residual volume
Abdominal distension or discomfort
Vomiting or diarrhea
Failure to implement evidence-based uniform algorithmic approach to EN
Delay in initiating EN

EN, enteral nutrition.

Protocols or algorithms have been employed in the PICU to ensure prompt institution of EN in eligible patients, followed by advancement of feeds to the goal and management of feeding intolerance. Fig. 87.4 describes an EN initiation and advancement protocol at a tertiary center. The implementation of this algorithm resulted in a significant increase in the number of patients reaching energy delivery goal in this PICU.[96] A significant decrease in the number of avoidable EN interruptions and use of PN was recorded after the implementation of this algorithm. Stepwise algorithms have been used by other investigators to facilitate optimal EN delivery in the PICU.[97,98] However, they are used in a minority of centers, and the actual components of the algorithms vary significantly.[99] The use of postpyloric feeding has been compared to gastric feeding in the PICU population. In a randomized control trial of mechanically ventilated children, the use of a postpyloric tube for feeding allowed a higher amount of nutrient delivery (percentage of caloric goal) compared to gastric tube feeding.[100] The incidence of aspiration of gastric contents as well as symptoms of EN intolerance was similar in the two groups. Postpyloric tubes provide the opportunity to feed a subset of children for whom intragastric feeding has not succeeded or is deemed unsafe. The use of the postpyloric route for feeding critically ill children is limited to centers with the appropriate resources and expertise for placement and management of these tubes. Surgical placement of gastrostomy or jejunostomy tubes allows long-term enteral feeding and administration of drugs in selected patients during intensive care and after discharge from the ICU. The advent of percutaneously placed gastric and jejunal tubes has minimized cost, time, and morbidity. Stoma site infection, obstruction, and tube dislodgment are common complications and must be identified and managed early. Tube tip malposition is frequently encountered with any of these devices either at placement or during the course of its use.

Immune-Enhancing Diets for the Critically Ill

Child

In 1996, Bone and colleagues[101] outlined the role of the compensatory antiinflammatory response (CARS), which follows the initial proinflammatory response by the body challenged with an insult or infection (see Chapters 81, 101, 102, and 105). The antiinflammatory response was believed to be the second phase of a biphasic, highly coordinated inflammatory response and was aimed at keeping the proinflammatory response under control. It is clear that immunomodulation plays a significant role in the nature of response to infectious insult and impacts outcome in children with sepsis admitted to the ICU (see Chapter 105). The role of nutrition has expanded beyond that of growth and rehabilitation. Newer components have been introduced in enteral feeds such L-arginine, glutamine, taurine, nucleotides, w-3 and w-6 fatty acids, carnitine, growth factors, probiotics, and prebiotics. These immune-enhancing diets (IEDs) have been available for many years, and their role in the care of critically ill patients remains controversial. An increasing number of studies examining the effect of IEDs in various clinical populations and related meta-analyses continue to provide conflicting conclusions. Methodological flaws in conducting initial studies and the heterogeneous nature of the IED formulations used do not allow for dispelling current doubts regarding the safety and efficacy of these diets. The commercially available diets contain a mixture of compounds in varying doses, and the role of individual compounds is impossible to interpret. The immunomodulating effects of individual compounds are dose dependent, and mixtures of different immunomodulating nutrients may have synergistic but also antagonistic effects. However, the compositions of the products compared in the meta-analysis are considerably different.

There are insufficient pediatric studies evaluating the role of nutrition-based immunonutrition in critically ill children. In a randomized double-blind comparative effectiveness trial, investigators sought to examine the impact of nutraceutical supplementation with zinc, selenium, glutamine, and metoclopramide on preventing nosocomial infection in children requiring long-term critical care.[102] The group who received immune-enhancing supplementation did not show difference in time to acquiring infection/sepsis when compared to the group with whey supplementation. In a subset of the cohort (9%) with immunocompromise, the intervention resulted in a reduction of nosocomial infection rates. In a 2 × 2 factorial trial, Heyland and colleagues randomized more than 1200 adults with multiorgan failure and mechanical ventilation to receive glutamine, antioxidants, both, or placebo.[89] The trial was stopped early as there was a trend toward increased 28-day mortality, significantly increased in-hospital mortality, and 60-month mortality in the patients who received glutamine as compared with those who did not receive glutamine. Glutamine supplementation was not associated with decrease in rates of organ failure or infectious complications. Antioxidant supplementation in this trial had no effect on 28-day mortality. The lack of beneficial effect of glutamine and association with increased mortality in this study has resulted in a significant lack of enthusiasm for the immunonutrition strategy for critically ill patients. Future studies may examine the role of other micronutrients and the impact of immunonutrition in improving outcomes in immunocompromised patients. The generalized use of immunonutrition in the PICU children cannot be recommended at this time.

Parenteral Nutrition

PN or hyperalimentation bypasses the gut, allowing intravenous administration of macronutrients and micronutrients to meet the nutritional requirements of the body, either partly (as a supplement to enteral feeds) or entirely (total PN). PN is indicated for children who are unable to tolerate enteral feeds for prolonged periods. In the setting of intact intestinal function, PN is not indicated if enteral feeds alone can maintain nutrition. Although widespread in its application, PN is associated with mechanical, infectious, and metabolic complications and hence should be used only in carefully selected patients. The timing of imitating PN in the ICU has been investigated. In a large randomized controlled trial (EPaNIC), 4640 patients were randomly assigned to receive parenteral nutrition within 48 hours of admission to the ICU (early PN) or received PN at 8 days or later after admission (late PN).[103] Patients from the group that received late PN were more likely to be discharged alive from the ICU within 8 days than were patients given early PN. No significant differences were reported in the ICU, hospital, and 90-day mortality between the groups. Furthermore, the late PN group had shorter duration of mechanical ventilation and hospital length of stay. Based on the results of this study, PN is used when EN is contraindicated or when EN is unable to meet macronutrient demands for approximately 7 days. In preterm infants, newborns, and those with malnutrition, PN may be initiated earlier. A randomized trial examining the role of early versus late PN (initiated after 7 days) in patients who are unable to reach caloric goals via the enteral route in the PICU environment is currently ongoing.[104] The results of this trial will help instruct the optimal timing of PN in critically ill children.

PN prescription, compounding, and delivery require vigilance to avoid errors that are inherent to each stage of this complex process. Institutions must ensure that PN is prescribed by individuals with appropriate competency, and a multidisciplinary approach with communication among the physician, dietitian, and pharmacist is essential to achieve safe PN delivery in the PICU. Fluid and electrolyte status guide the initial PN prescription. Fluid restrictions limit the amount of calories delivered despite use of a concentrated formula. PN should not be used for replacing ongoing losses. PN should be prescribed daily and after reviewing levels of electrolytes and blood sugar in order to allow adjustments in the macronutrient and micronutrient composition. The patient's hydration, size, age, and underlying disease dictate the amount of the fluid to be administered. Table 87.8 describes the calculations used to determine calories provided from macronutrients in PN.

TABLE 87.8

Calculating Parenteral Nutrition calories

Total carbohydrate (CHO) in g/day x 3.4 kcals/g = CHO calories
1 g dextrose provides 3.4 kcals (most other CHOs provide 4 kcals/g)
10% dextrose = 10 g dextrose/100 mL
Total protein in g pro/day x 4 kcals/g = protein calories
1 g protein provides 4 kcals
Total fat (20% lipids) in mL x 2.0 kcals/mL = lipid calories
(10% lipids = 1.1 kcal/mL)
Total calories = CHO + protein + lipid calories
Total nonprotein calories = CHO + lipid calories

Carbohydrates

Carbohydrates are the major nonprotein source of energy. D-Glucose is provided in the monohydrate form for intravenous administration and yields 3.4 kcal/g. The concentration of the dextrose solution should not exceed 10% for peripheral administration. In the setting of central venous access, a range of concentrations (5% to 40%) can be prepared. Higher glucose concentration makes the solutions hyperosmolar and may cause phlebitis or thrombosis and decrease the life span of the vessel when PN is administered peripherally through a vein. Blood glucose estimations must be followed carefully given the increased incidence of hyperglycemia, especially in young infants. Carbohydrate is started at 5 to 8 mg/kg/min. Gradually increasing the carbohydrate load allows appropriate endogenous insulin response and prevents fluctuations in blood sugar. Abrupt cessation of PN may result in hypoglycemia and should be anticipated and avoided.[105] Fat is supplied as Intralipid, which provides the other source of calories in PN and reduces the carbon dioxide production and water retention that is seen when carbohydrate is the sole source of calories.

Amino Acids

One gram of protein yields 4 kcal. Initial recommended dosages range from 0.5 to 3 g/kg/day based on age, disease state, and individual requirements. Usual concentrations available are between 1% and 4%, although patients with hepatic disease, renal insufficiency, and children with metabolic diseases (eg, maple syrup urine disease) should receive appropriately modified concentrations. Trophamine contains a higher percentage of branched-chain amino acids and a small amount of glycyl-cysteine. This solution is mainly used in the neonatal population. It is recommended and used in patients with hepatic encephalopathy and in children on long-term PN (eg, short bowel), although data supporting this application are scarce. There is an increasing interest in the use of glutamine in PN. Glutamine and cysteine as glycyl-cysteine are precursors for glutathione, which is a major antioxidant. Glutamine is also a precursor for nucleotide synthesis, and although it is a nonessential amino acid, it can become conditionally essential, especially in catabolic states such as sepsis and trauma. Glutamine has a short shelf life. However, its applicability has been widespread. It has been introduced in PN solutions for its presumed benefits, such as restoration of protein and nitrogen balance, attenuation of gastrointestinal mucosal atrophy, reduction of bacterial translocation, and bacteremia after chemotherapy. The National Institute of Child Health and Development (NICHD) neonatal research network did not find significant differences in outcomes when a multicenter study randomized 1430 extremely low-birth-weight neonates to PN containing 20% glutamine or an isonitrogenous control. However, pediatric burn patients have been shown to have deficient peripheral glutamine production. In a double-blinded randomized control trial, glutamine-enhanced PN reduced gram-negative bacteremia in severely burned patients.[106]

Lipids

Lipids are an integral part of PN and provide energy through fatty acid oxidation. Lipids are usually started at 0.5 to 1 g/kg and advanced to a maximum intake of 3

g/kg or a maximum 60% of total kilocalories. Lipid calories allow for lower concentration of carbohydrate (lower osmolarity of PN). Lipid emulsions are available as 10% (1.1 kcal/mL) or 20% (2 kcal/mL). Intralipid prevents or treats essential fatty acid deficiency. The total lipid usually is delivered over an 18- to 24-hour period through separate tubing using a Y connector near the infusion site. Delivery of amino acid, glucose, and lipid (three-in-one) is no longer recommended for neonatal patients because of the risk of calcium phosphate precipitation being obscured by lipid in the preparation.

Lipids are a crucial source of nutrition in parenteral formulas. Traditionally considered a calorie-dense nutrient and a source of essential fatty acids, lipids in intravenous feeding regimens have added advantages, such as providing a more balanced energy expenditure and facilitating better respiratory function parameters. Fatty acid derivatives are major biological modulators.[107] Fig. 87.5 illustrates the basic pathways and inflammatory effects of fatty acid metabolites. The linoleic acid load, as a consequence of predominantly soy-based lipid in current formulations, results in increased arachidonic acid production and decreased production of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA).[108] Increased arachidonic acid levels may increase the proinflammatory cytokine production and activity. EPA levels may influence the production of antiinflammatory cytokines,[107] and DHA has been shown to lower blood pressure, improve endothelial function, and elevate levels of high-density and low-density lipoproteins.[109] Thus DHA and EPA, found in fish and fish oils, are essential fatty acids for humans. In an attempt to decrease the linoleic acid intake, soy-based oil has been partly replaced by medium-chain triglycerides, olive oil, or fish oil in intravenous emulsions. Based on the putative advantages of fish oils as immune modulatory agents, they have been applied in clinical trials across a wide spectrum of critically ill patients.[34,86] The OMEGA trial was a double-blinded multicenter placebo-controlled trial where subjects received twice-daily enteral supplementation with omega-3 fatty acids, γ-linolenic acid, and antioxidants compared with an isocaloric control.[110] The trial was stopped early due to futility. The supplemented group did not show any improvement in the primary outcome of ventilator-free days and rather appeared to have a higher incidence of harm compared to the control group. There are currently no pediatric data to support the use of omega-3 fatty acid supplementation in the PICU.

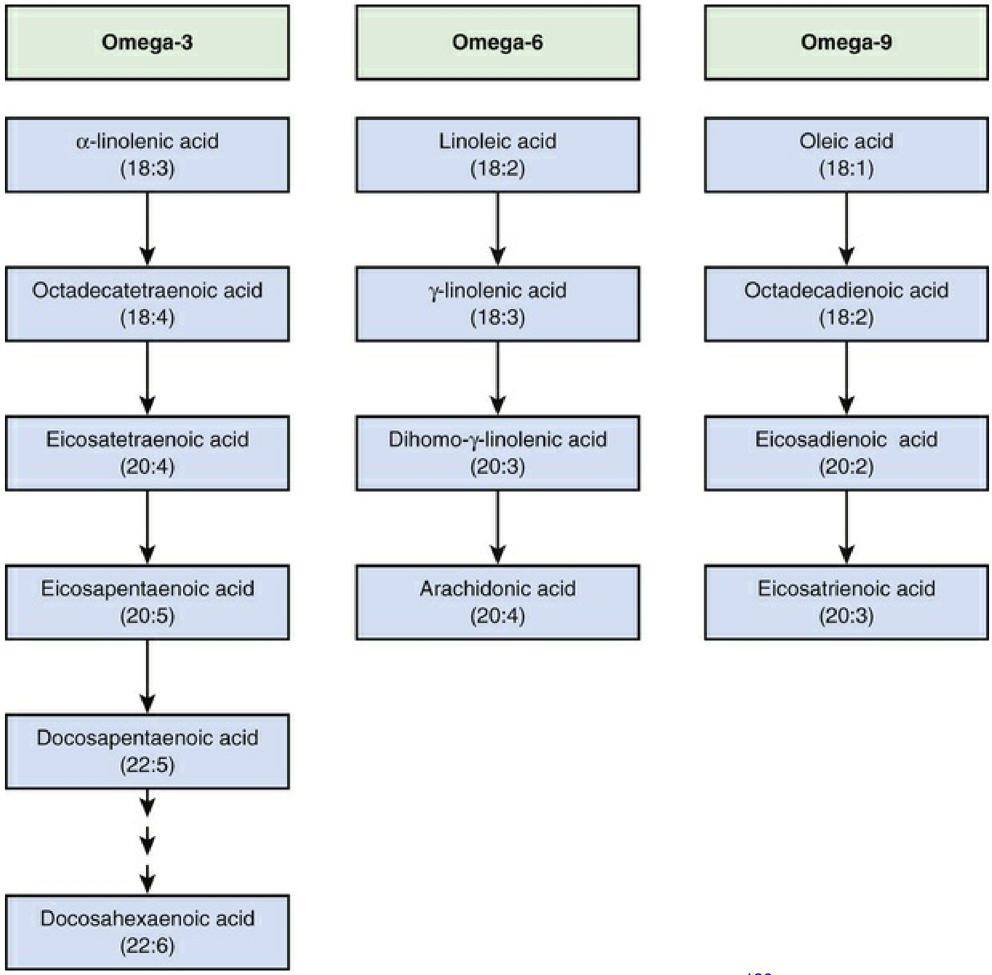

FIG. 87.5 Omega-3 and omega-6 fatty acid metabolites.[120] (Adapted from Lee S, et al. Current clinical applications of omega-6 and omega-3 fatty acids. Nutr Clin Pract. 2006;21:323-341.)

Electrolytes/Minerals and Trace Elements

All solutions typically are prepared with minimum acetate (ie, all salts are added as chloride) unless prescribed otherwise. It is possible to prescribe an all-acetate solution with no chloride. Calcium and phosphorus precipitate when their concentrations exceed an allowable limit, related to the solubility index of $(Ca)_3(PO_4)_2$ and the pH of the solution. Selenium may not be routinely added to PN. A serum selenium level is obtained if a patient requires PN for more than 30 days without enteral intake. Multivitamins and trace elements are routinely added to the PN, and recommended intakes are elucidated elsewhere.[111] Heparin usage in PN is practiced in many centers and has been shown to decrease catheter-related sepsis.[112] Heparin in concentrations of 0.5 to 1 U/mL are thought to prevent thrombosis and possibly phlebitis in peripheral lines, although there are no controlled trials showing significant benefit of heparin usage in PN.

Biochemical Monitoring

A PN profile is recommended at initiation of therapy and weekly thereafter. The profile includes serum levels of sodium, potassium, chloride, glucose, carbon

dioxide, blood urine nitrogen, creatinine, albumin, magnesium, phosphate, total and direct bilirubin, and transaminases. For children requiring PN for more than 30 days, selenium, iron, zinc, copper, and carnitine levels should be checked. Daily vital statistics and routine anthropometry must be monitored to ensure adequate growth and development. Critical care units benefit from the expertise of a dedicated nutritionist, who should be consulted on a regular basis to guide optimal nutritional intake of patients.

Central venous access is required for delivery of hyperosmolar PN solutions into a large-bore vein with high-volume blood flow to prevent thrombosis and phlebitis (see Chapter 19). The incidences of infective and life-threatening complications related to indwelling central lines have necessitated extreme caution with central PN use.[113,114] Central lines should be placed by experienced operators and line tip position confirmed by radiography before the lines are used for PN delivery. It is recommended that central line tips be positioned outside the cardiac chambers at all times. Central lines are recommended for delivery of infusates with osmolarity greater than 900 mOsm/L (10% dextrose, 2% amino acids with standard additives).

Nutritional Support of Obese Critically Ill Children

Overweight/obesity continues to increase in children and adolescents, and annual obesity-related hospital costs in 6- to 17-year-olds have reached $127 million per year. Obesity may be a risk factor for higher mortality in children with critical illness, particularly those with oncologic diseases or undergoing organ transplantation.[115] The severity of obesity is classified based on BMI into the following three categories: (1) overweight = BMI 25 to 30 kg/m^2, (2) obesity = BMI 30 to 40 kg/m^2, and (3) morbid obesity = BMI >40 kg/m^2. Overweight children and adolescents are increasingly being diagnosed with impaired glucose tolerance and type II diabetes, and they show early signs of the insulin resistance syndrome and cardiovascular risk. Centralized distribution of body fat is associated with the risk of metabolic syndrome. Metabolic syndrome is observed in obese children and is characterized by visceral obesity, insulin resistance, and dyslipidemia. There is a high risk for type II diabetes and cardiovascular complications in patients with metabolic syndrome. Grossly overweight patients are prone to sleep apnea syndrome, restrictive lung disease, venous thrombosis, musculoskeletal degenerative disorders, hepatic steatosis, and metabolic disorders associated with bariatric surgery. The metabolic response to stress in obese critically ill patients is complex, given that it occurs in a population with preexisting major metabolic and endocrine alterations. In critically ill obese patients, the pattern of substrate oxidation is mainly protein and glucose, with decreased fat oxidation.[116] The extent of protein breakdown is greater than in nonobese critically ill adults. No data on metabolic abnormalities of obese children are available. In the adult critically ill population, hypocaloric nutrition estimated for ideal weight has been recommended.[117] The limited adult literature suggests that protein requirements are higher in critically ill adult obese patients. It is recommended that fat be administrated sparingly, mainly to prevent essential fatty acid deficiency.[118] Evidence for the best nutritional support strategy for critically ill obese children is

not currently available. Routine equations for tend to overestimate energy expenditure in obese patients.[119] Energy requirements in this group should be guided by IC measurement of REE, where available. When REE is estimated, there is no consensus on the use of ideal body weight versus adjusted body weight. As the incidence of obesity in children admitted to the PICU is rising, future research aimed at addressing some of these knowledge gaps is desirable.

Guidelines for Pediatric Critical Care Nutrition

Due to the complexities of critical care, nutrient intake during critical illness is challenging. The lack of robust evidence for many of the bedside decision making around nutrition support in the PICU has resulted in heterogeneity in practice. Optimal nutrition support in the PICU cannot be achieved unless there is some uniformity in practice based on evidence or consensus and an attempt to systematically evaluate practice parameters for feasibility, efficacy, and impact on patient outcomes. However, the direct effect of nutritional strategies in a heterogeneous cohort of patients with varying degrees of illness severity is difficult to assess. Multiple factors influence outcome during critical illness. Due to these challenges, current literature is scarce and guidelines for pediatric critical care nutrition have been based on few good studies but mainly smaller studies of expert opinion. In 2009, the American Society of Parenteral and Enteral Nutrition published the revised guidelines for pediatric critical care nutrition practice (Table 87.9).[52] These guidelines were based on best available evidence and help clarify the principles guiding nutrition therapy in the PICU population. Early enteral nutrition is recommended in critically ill children with a functional gastrointestinal tract. Careful assessment or measurement of energy expenditure with attention to unintended energy imbalance (due to underfeeding or overfeeding) seems prudent. Health care workers must work in a collaborative fashion to identify and prevent common barriers to nutrition support in the PICU. The application of indirect calorimetry and postpyloric feeding is currently limited to centers with available expertise and resources.

TABLE 87.9

Guidelines for Pediatric Critical Care Nutritional Support[52]

NUTRITION SUPPORT GUIDELINE RECOMMENDATIONS IN THE CRITICALLY ILL CHILD		
#	Guideline Recommendations	Grade
1	1A. Children admitted with critical illnesses should undergo nutrition screening to identify those with existing malnutrition and those who are nutritionally at risk.	D
	1B. A formal nutrition assessment with the development of a nutrition care plan should be required, especially in those children with premorbid malnutrition.	E
2	2A. Energy expenditure should be assessed throughout the course of illness to determine the energy needs of critically ill children. Estimates of energy expenditure using available standard equations are often unreliable.	D
	2B. In a subgroup of patients with suspected metabolic alterations or malnutrition, accurate measurement of energy expenditure using indirect calorimetry (IC) is desirable. If IC is not feasible or available, initial energy provision may be based on published formulas or nomograms. Attention to imbalance between energy intake and expenditure will help to prevent overfeeding and underfeeding in this population.	E
3	There are insufficient data to make evidence-based recommendations for macronutrient intake in critically ill children. After determination of energy needs for the critically ill child, the rational partitioning of the major substrates should be based on understanding of protein metabolism and carbohydrate and lipid handling during critical illness.	E

4	4A. In critically ill children with a functioning gastrointestinal tract, enteral nutrition (EN) should be the preferred mode of nutrient provision, if tolerated.	C
	4B. A variety of barriers to EN exist in the pediatric intensive care unit (PICU). Clinicians must identify and prevent avoidable interruptions to EN in critically ill children.	D
	4C. There are insufficient data to recommend the appropriate site (gastric vs. postpyloric/transpyloric) for enteral feeding in critically ill children. Postpyloric or transpyloric feeding may improve caloric intake when compared to gastric feeds. Postpyloric feeding may be considered in children at high risk of aspiration or those who have failed a trial of gastric feeding.	C
5	Based on the available pediatric data, the routine use of immunonutrition or immune-enhancing diets/nutrients in critically ill children is not recommended.	D
6	A specialized nutrition support team in the PICU and aggressive feeding protocols may enhance the overall delivery of nutrition, with shorter time to goal nutrition, increased delivery of EN, and decreased use of parenteral nutrition. The effect of these strategies on patient outcomes has not been demonstrated.	

From Mehta NM, Compher C. A.s.p.e.N. Clinical guidelines: nutrition support of the critically ill child. JPEN J Parenter Enteral Nutr. 2009;33:260-276.

Conclusions

Accurate assessment of nutritional needs and the provision of individually tailored optimal nutrition support to the critically ill child are important goals of pediatric critical care. Malnutrition and obesity are prevalent in the PICU and have significant influence on the outcome of critical illness. Furthermore, the hypermetabolic stress response places demands on the critically ill child that must be met with evidence-based nutrient supplementation. Intensivists must remain alert to the possibility of both underfeeding and overfeeding in order to prevent unintended cumulative energy imbalances in critically ill children. Evidence suggests a significant relationship between inadequate protein intake and poor outcomes from critical illness. A multidisciplinary effort to overcome common barriers to nutrient delivery and the use of evidence-based algorithms will help achieve nutrition goals in the PICU.

Interest in the immune-modulating effects of nutrients, micronutrient supplementation, and the role of newer sources of lipid formulations has introduced the concept of pharmaconutrients, but the benefits on outcome in the PICU have not been realized yet. The feasibility of strict glycemic control in the PICU is currently being examined in the setting of a randomized control study. In the future, patients will benefit from individually tailored nutritional regimens suited to the type and stage of their illness. There are a number of knowledge gaps in the field of critical care nutrition that need to be addressed by collaborative research. Until then a multidisciplinary effort must be made to increase awareness of nutritional issues and prioritization of nutrition support in the PICU.

SECTION VII

Hematology-Oncology

OUTLINE

CHAPTER 88

Structure and Function of Hematopoietic Organs

Seth J. Corey, Julie Blatt

PEARLS

- Normal ranges for blood cell numbers or function depend on the age of the patient.
- Hematopoiesis in a given bone varies with age and must be considered for successful bone marrow aspiration or biopsy.
- Because the marrow circulation connects with the general circulation, fluids and medications injected into bone marrow are absorbed as rapidly as when they are administered intravenously.
- For major invasive procedures such as surgery or placement of arterial lines or endotracheal tubes, platelet count should be maintained at ≥50,000/μL.
- Clinical application of small molecule regulators of hematopoiesis is increasing.

Poised to maintain homeostasis, the hematopoietic system must respond quickly to changes in oxygen tension, bleeding, or infection by increasing the production of erythrocytes, platelets, or neutrophils. When stressed, especially in a very ill neonate or child, hematopoiesis and blood cell function may be insufficient. Alternatively, excessive or poorly controlled leukocytes lead to autoimmunity, macrophage activation syndromes, or chronic inflammation. The extensive use of red blood cell (RBC) or platelet transfusions and antimicrobials supports the importance of the blood system as a vital organ affected in the pediatric intensive care unit setting. This chapter reviews the anatomy and physiology of the hematopoietic system to provide a basis for understanding the repercussions of primary hematologic abnormalities, as well as hematopoietic manifestations of nonhematologic diseases. Aspects that are of practical importance to the intensivist are emphasized.

Structure and Function of the Bone Marrow

During embryogenesis and fetal development, hematopoiesis shifts from the yolk

sac (primitive hematopoiesis) to the liver and, after 20th week of gestation, to the bone marrow (definitive hematopoiesis).[1] Although extramedullary erythropoiesis may persist for several weeks after birth, in the term infant hematopoiesis takes place almost entirely in the bone marrow. A defining feature of hematopoietic stem cells is their ability to home to the bone marrow. This homing occurs via chemoattractants such as stromal cell-derived factor-1 and its cognate receptor CXCR4 on the stem cell, as well as interaction between a variety of stem cell adhesion molecules and their ligands on stroma and endothelial cells. Compartments of hematopoietic stem, progenitor, and precursor cells may be identified by the presence of cell surface markers. In particular, the hematopoietic stem cells are identified by the cell surface expression of CD34 and the ability to exclude Hoechst dye 33342 via a multidrug transporter.[2]

Grossly, two types of bone marrow can be recognized in normal individuals: yellow marrow, so called because of the predominance of adipocytes, and red marrow, in which blood cells predominate. White marrow, consisting predominantly of stromal cells and intercellular matrix, may result from atrophy or starvation. Red marrow proportionately is a much greater component of body weight and volume in the infant than in the adult (Fig. 88.1).[3] Early in life, it is contained in the medullary cavities of the long bones, which gradually fill with fat such that by late puberty, the adult distribution of hematopoiesis (sternum, pelvis, vertebrae, cranium, ribs, epiphyses of long bones) is achieved. That the degree of hematopoiesis in a given bone varies with age is an important consideration in selecting a site for bone marrow aspiration or biopsy; for example, although the anterior and posterior iliac crests can be used at any age, the tibia can be used only until the age of 2 years. In disease states characterized by excessive destruction of blood cells, such as severe hemolytic anemias, hematopoiesis may increase twofold to eightfold. Active sites of hematopoiesis may expand and can result in frontal bossing of the skull, which is characteristic in children with untreated thalassemia major. Extramedullary hematopoiesis may be found, particularly in the liver and spleen.

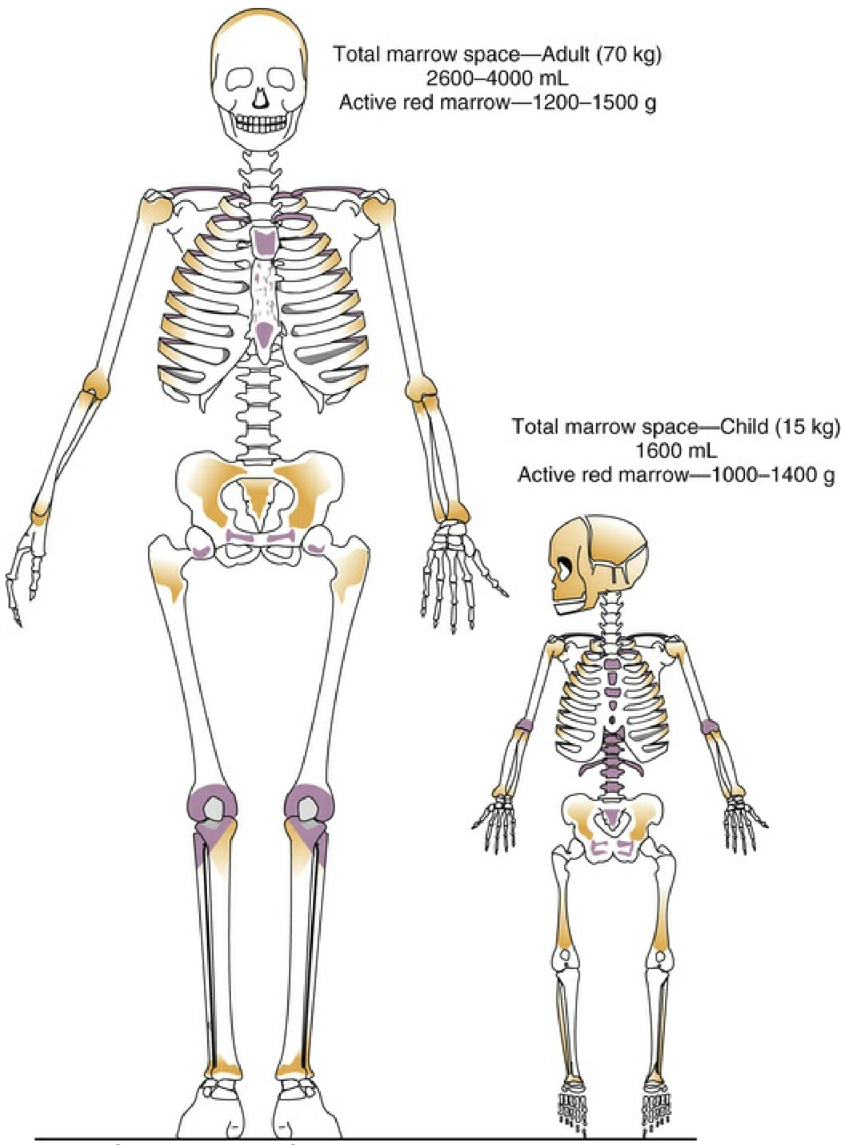

FIG. 88.1 Comparison of active red marrow–bearing areas in the child and the adult. Note the almost identical amount of active red marrow in the child and adult despite a fivefold discrepancy in body weight. (Modified from MacFarlane RC, Robb-Smith AHT. Functions of the Blood. Oxford: Blackwell; 1961.)

Microscopically, the marrow is a network of vascular channels (sinuses) separating islands of fat, hematopoietic cells, and rare osteoblasts and osteoclasts (which are important for bone remodeling).[4,5] The vasculature and cells are joined by a reticulin (fiber) network or scaffolding. By light microscopy, bone marrow aspirate specimens demonstrate hematopoietic elements; however, a bone marrow biopsy provides a more accurate measure of cellularity. Reticulin can be seen by light microscopy with histochemical staining, and it suggests myelofibrosis, either a primary or secondary.

The blood vessels that feed the marrow are branches of those that feed the surrounding bone.[4,6] Large central arteries run longitudinally within the marrow and send radial branches that penetrate the endosteum and form capillaries in the Haversian and Volkmann canals of the bony cortex.[4] These capillary systems drain into the bone marrow sinuses, which in turn drain into a central sinus or vein. Because the marrow circulation connects with the general circulation in this fashion,

fluids and medication injected in bone marrow are absorbed as rapidly as through intravenous routes. Unlike peripheral veins, intramedullary vessels supported by their bony shell do not collapse in shock; therefore intraosseous (either tibial or iliac crest) infusion is appropriate when peripheral intravenous access is not available (see also Chapter 19).[7] It is also noteworthy that the connection between the marrow and general circulation provides the mechanism by which bone marrow may embolize to the lung after osseous trauma or fracture. This has not been demonstrated to be of clinical significance in the case of intraosseous infusion.[8]

The concept of the stem cell has expanded recently,[9,10] and its ex vivo manipulation has raised much interest by a wide group of physicians and scientists studying nonhematologic systems. One essential feature of the stem cell is its plasticity.[11] Provocative studies have shown that stem cells isolated from the bone marrow can be driven to differentiate to muscle, liver, cardiac, or neuronal tissue. In addition, differentiated cells may be isolated from patients and be reprogrammed to become an induced pluripotent stem cell (iPSC) through transient expression of stem cell transcription factors. These approaches raise the possibility that the marrow may be a convenient and ethically less challenging source of stem cells for stem cell engineering and tissue replacement. Although the clinical applications to nonhematologic tissues remain distant, the use of hematopoietic stem cells to replace a diseased marrow is a common practice (ie, stem cell transplantation) (see also Chapter 95). Alternative sources of hematopoietic stem cells have been found in peripheral blood following growth factor–induced mobilization or from placental cord blood.

Hematopoiesis

Bone marrow cells include the RBCs, granulocytes (neutrophils, eosinophils, basophils), monocytes and macrophages, platelets, lymphocytes, and their precursors. Hematopoietic stem and progenitor cells look like small lymphocytes and are not usually distinguishable from them by microscopy. Their existence, which constitutes less than 1% of the marrow population, was best confirmed by in vitro culture assays in which nucleated cells from bone marrow aspirate specimens plated onto tissue culture dishes layered with methylcellulose generate colonies (aggregates of cells) of one or more lineages. Now, immunophenotyping provides rapid identification of cell lineage and stage of development.[12] The first morphologically identifiable precursor cells are the proerythroblast, myeloblast, monoblast, megakaryoblast, and lymphoblast. These committed precursors and their terminally differentiated counterparts sit within the hematopoietic islands. Megakaryocytes (which make up <1% of hematopoietic cells) generally are located next to marrow sinusoids and shed platelets (fragments of megakaryocyte cytoplasm) directly into the lumen. Erythroblasts also are produced near the walls of the vascular sinuses in clusters with macrophages called erythroblast islets. As the erythroblasts develop, they extrude their nuclei, which are phagocytosed by the macrophages. During severe stress-induced erythropoiesis (eg, hypoxia and severe hemolytic anemia) or when the marrow space is disrupted by tumor cell infiltration, circulating nucleated RBCs may be observed. In contrast, granulocytes (the most numerous cell found in the bone marrow), monocytes, and lymphocytes are produced throughout the marrow away from vascular sinuses. The mature white

blood cells (WBCs) are motile and migrate to the sinuses.

Within the peripheral circulation, the number of cells of each type is maintained in a narrow range in the normal individual. Adults and postpubertal adolescents have approximately 5000 granulocytes, 2000 lymphocytes, 500 monocytes, 5×10^6 RBCs, and 150,000 to 300,000 platelets per microliter of whole blood. Age-dependent values for younger children are shown in Table 88.1.[13] To a lesser extent, values are also a function of race and sex, so that African Americans (especially males) normally may have granulocyte counts less than 1500/μL. Normative values for Latinos are less clear but have been reported to be closer to those of Caucasians.[14] Under normal conditions the rate of production of each cell type equals the rate of destruction. Because the life span of mature RBCs in adults is 100 to 120 days, 5×10^4 RBCs/μL are produced daily. The average platelet life span is 7 to 10 days so that approximately 2×10^4 platelets/μL are produced daily. Granulocytes production occurs at a rate of 10^4 cells/μL/day, but their life span remains unsettled with estimates from hours to up to 5.4 days. The very slow rate of production of lymphocytes reflects their long life span, measured in years.

TABLE 88.1

Normal Values for Hematology

Age	Hemoglobin (g %)	Hematocrit (%)	Mean Corpuscular Volume (fl)	MCHC (g/%RBC)	Reticulocytes (%)	WBC/μL × 100 Range (avg)	% Neutrophils	Platelet (10^3/μL)
28-week gestation	14.5	45	120	31	5-10	—	—	275 ± 60
32-week gestation	15.0	47	118	32	3-10	—	—	290 ± 70
1 day*	16.8-21.2	57-68	110-128	29.7-33.5	1.8-4.6	7-35 (18)	45-85	310 ± 68
1 week*	15.0-19.6	46-62	107-129	30.4-33.6	0.1-0.9	4-20 (10)	30-50	
1 month*	11.1-14.3	31-41	93-109	33.3-36.5	0.1-1.7	6-18 (10)	30-50	
3-5 months	10.4-12.2	33	80-96	31.8-36.2	0.4-1.0	6-17 (10)	30-50	300 ± 50
6-11 months	11.8	35	77	33	0.7-2.3	6-16 (10)	30-50	
1 year	11.2	35	78	32	0.6-1.7	6-15 (10)	30-50	
2-10 years	12.8	37	80	34	0.5-1.0	7-13 (9)	35-60	
11-15 years	13.4	39	82	34	0.5-1.0	5-12 (8.5)	40-60	
Adult								300 ± 50
Male	16.0 ± 2.0	47 ± 7	91	34	0.8-2.5	4.3-10 (7)	25-62	
Female	14.0 ± 2.0	42 ± 5	(82-101)	(31.5-36)	0.8-4.1			

*Under 1 month of age, capillary hemoglobin exceeds venous hemoglobin: 1 hour, 3.6 g difference; 5 days, 2.2 g difference; 3 weeks, 1.1 g difference.

Absolute eosinophil count: average 250/μL (100-600/μL).

MCHC, mean corpuscular hemoglobin count.

Data from Guest GM, Brown EW. Erythrocytes and hemoglobin of the blood in infancy and childhood. III. Factors in variability, statistical studies. Am J Dis Child. 1957;93:486; Matoth Y, et al. Postnatal changes in some red cell parameters. Acta Paediatr Scand. 1971;60:317; Wintrobe MN. Clinical Hematology. ed 7. Philadelphia: Lea & Febiger; 1974; Mauer AM. Pediatric Hematology. New York: McGraw-Hill; 1961; Oski FA, Naiman JL. Hematologic Problems in the Newborn Infant. Philadelphia: WB Saunders; 1972; and Nathan D, Oski F. Hematology of Infancy and Childhood. Philadelphia: WB Saunders; 1981.

The mechanisms that regulate this steady state are incompletely understood. However, evidence strongly suggests the existence of a pluripotent stem cell that is capable of self-renewal, from which progenitor cells committed to hematopoiesis

(RBCs, granulocytes, megakaryocytes, and monocytes) and to lymphopoiesis develop (Fig. 88.2).[13] The "trilineage myeloid" stem cell has been designated *colony forming unit-stem* (CFU-S) on the basis of bone marrow culture assays and experiments in which the spleens of lethally irradiated mice infused with donor marrow cells are found to contain colonies each consisting of precursors of RBCs, granulocytes, monocytes, and megakaryocytes.[15] The existence of CFU-S in humans is supported by chromosomal studies in myeloproliferative disorders. Lymphoid development appears to arise from a separate progenitor. Although the CFU-S is found predominantly in the bone marrow, there probably are small numbers of circulating pluripotent stem cells because it has long been known that marrow of lethally irradiated animals can be reconstituted with unmanipulated peripheral blood.[16]

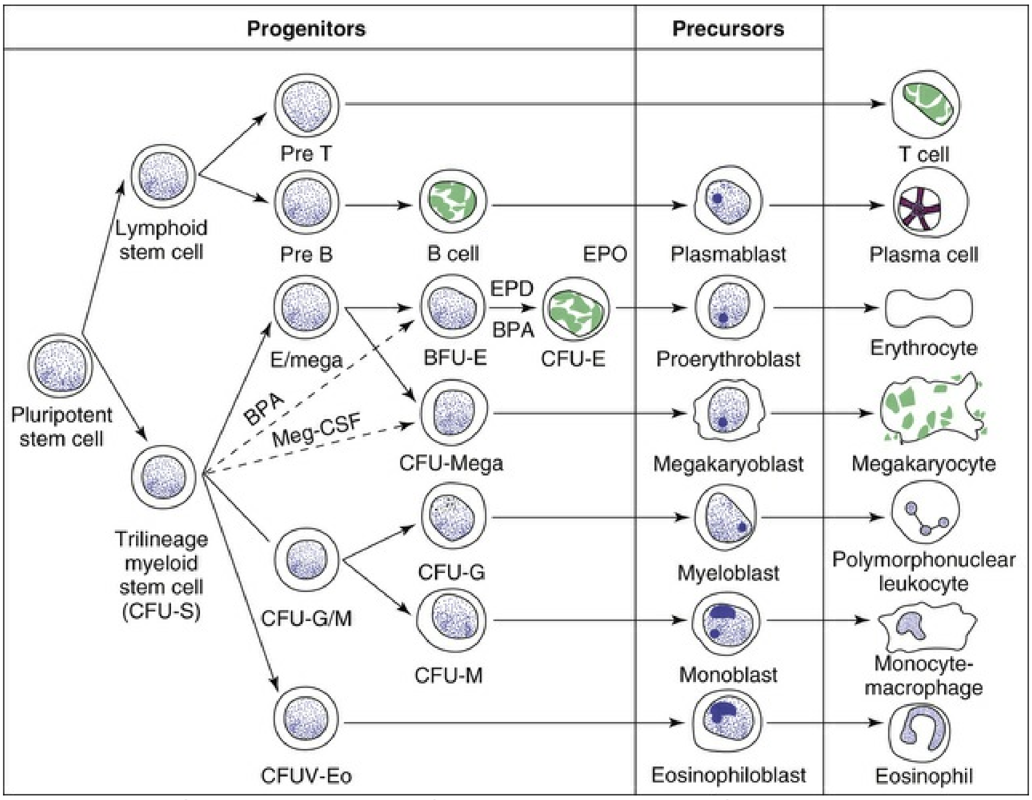

FIG. 88.2 Schematic outline of the progenitor basis of hematopoiesis. Not shown in this outline is the process of self-renewal of fractions of the progenitor cell populations, particularly the immature progenitors. Also not shown is the progressive amplification of progenitors and precursors as they mature and differentiate. The bipotential erythroid-megakaryocyte progenitor shown in this drawing has been demonstrated in the mouse but not definitively in humans. *Dotted arrows* indicate an alternative scheme. (Modified from Nathan DG. Introduction: hematologic diseases. In: Wyngaarden JB, Smith JH, eds. Cecil's Textbook of Medicine. Philadelphia: WB Saunders; 1988.)

The number of committed progenitor cells that differentiate in any time period is dependent on feedback from humoral regulators that are produced within the marrow microenvironment and by extramedullary sources, including T cells, macrophages, endothelial cells, and fibroblasts. These hematopoietic growth factors

are cytokines. Many of the cytokines have overlapping functions. However, gene targeting in the mouse (“knockout mouse”) of cytokines or their cognate receptors has identified the essential nonredundant functions for several hematopoietic growth factors. Mice deficient in erythropoietin (Epo), thrombopoietin (Tpo), and granulocyte colony-stimulating factor (G-CSF) suffer from severe anemia, thrombocytopenia, or neutropenia, respectively.

The list of cytokines and small molecules that regulate hematopoiesis and their clinical application continue to grow. Chemical modification of Epo and G-CSF has resulted in two longer-acting forms, darbepoetin alpha and pegfilgrastim, respectively. Their primary advantage is longer half-lives. In lieu of thrombopoietin, two platelet-stimulating agents, romiplostim and eltrombopag, have been approved by the Food and Drug Administration (FDA) for use in adults with chronic immune thrombocytopenic purpura (ITP). Eltrombopag has also been approved for treatment of severe aplastic anemia in adults. Both drugs have been used in phase II clinical trials in pediatrics.[17] Characteristics of specific hematopoietic growth factors, discussed in the following sections, are summarized in Table 88.2.

TABLE 88.2

Recombinant Hematopoietic Growth Factors

CSF	Target	Clinically Available
SCF	HSC, mast cells	No
IL-3	HSC	No
Epo	Erythroid progenitors	Yes
G-CSF	Granulocytes and their precursors	Yes
GM-CSF	Phagocytes and their precursors, dendritic cells	Yes
M-CSF	Monocytes and their precursors	No
Tpo*	Megakaryocytes	Yes*
IL-11	Megakaryocytes	Yes

*Thrombopoietin receptor agonists, romiplostim and eltrombopag, are approved.

Epo, erythropoietin; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; HSC, hematopoietic stem cells; IL, interleukin; M-CSF, macrophage colony-stimulating factor; SCF, stem cell factor; Tpo, thrombopoietin.

Erythropoiesis

On its way toward RBC maturation (see Fig. 88.2), the CFU-S sequentially differentiates into burst-forming units-erythroid (BFU-E) and colony forming units-erythroid (CFU-E), which are identifiable experimentally on the basis of growth characteristics in culture. These phases of development, which involve amplification of cell number, are extensively reviewed elsewhere.[18] As noted earlier, the proerythroblast is the earliest morphologically identifiable precursor and presumably is the successor to the CFU-E. The subsequent sequence of RBC production normally takes 3 to 4 days in the marrow and involves multiple cell divisions with increasing differentiation, characterized chiefly by globin messenger RNA, cytoplasmic synthesis of hemoglobin, and ultimately extrusion of the RBC nucleus. The enucleated cell is large and, because it contains residual RNA, stains deeply by the Wright-Giemsa technique (ie, polychromatophilic macrocyte). Normally at this stage the erythrocyte is released into the circulation where it can be demonstrated as a reticulocyte. In newborns younger than 1 week of age,

reticulocytes in the blood can comprise more than 5% of the total RBCs. At any older age, the normal reticulocyte count is less than 2%. From this uncorrected reticulocyte count, the absolute reticulocyte count can be calculated by multiplying by the RBC count. The normal absolute reticulocyte count would be 0.02 to 5×10^6 RBC/μL. Alternatively, a corrected reticulocyte count is used, as determined by multiplying the reticulocyte percentage by the observed hematocrit divided by the normal hematocrit. If the corrected reticulocyte count is less than 1%, one must suspect bone marrow failure or insufficiency. Because the reticulocytes lose their RNA within 24 to 30 hours, their quantitation provides a rough estimate of the rate of erythropoiesis during the past 24 hours. This can be more accurately measured by ferrokinetic studies, but these are not readily available. The proportion of erythroid precursors in a bone marrow aspirate also provides a more convenient estimate of total erythropoiesis that is valid if a cellular specimen is obtained and if granulopoiesis is normal. In the older child or adult, erythroid precursors normally are one-third as plentiful as myeloid precursors (ie, the myeloid/erythroid ratio is about 3 : 1). Approximately 10% of erythroid precursors do not produce circulating RBCs (ineffective erythropoiesis).

Maturation of RBC precursors is regulated by a number of humoral and nutritional factors. Epo appears to act predominantly by increasing proliferation of CFU-E (see Table 88.2 and Fig. 88.2). Its production is stimulated by hypoxemia or acute hemorrhage. During fetal development, it is mainly produced in the liver, but this site shifts later to the juxtamedullary region in the kidneys. Humoral factors less well characterized than Epo that are derived from multiple sources (spleen cells, peripheral blood monocytes, and mononuclear bone marrow cells) appear to act at an earlier stage of differentiation to amplify the number of progenitors committed to Epo responsiveness. Among these are burst-promoting activity, which enhances production and proliferation of BFU-E. Within the marrow, normal RBC maturation requires both folate and vitamin B_{12}; a deficiency of either results in abnormal nucleic acid synthesis and the production of an abnormal precursor, the megaloblast. Iron is required for hemoglobin synthesis, and deficiency results in poorly hemoglobinized small (hypochromic, microcytic) RBCs.

Once in the peripheral blood, the life span of the normal RBC in the adult or older child is 100 to 120 days. In the term newborn, the RBC life span is about 60 days, which progressively diminishes with increasing prematurity.[15] Presumably these differences in age-dependent RBC longevity reflect differences in membrane stability and oxidative stress. Removal of RBCs from the circulation is not a random process. Senescent RBCs are removed selectively from the circulation by the macrophages of the reticuloendothelial system. Although this is primarily a function of the spleen (see the following section), asplenic patients with normal RBCs accomplish this process in the liver and other sites and do not exhibit an increased RBC life span. In subjects with hemolytic anemias who undergo therapeutic splenectomy, the red cell life span increases, but not to normal levels.

The primary function of the circulating RBC is to carry O_2 from the lungs to the tissues. Hemoglobin (Hb) must be packaged within the RBC membrane to prolong its plasma half-life. Interference with the reversible binding of O_2 by Hb can occur by several mechanisms, including (1) methemoglobinemia, the inability to maintain ionic iron within the Hb molecule in the reduced (ferrous, Fe^{++}) state; (2) the presence

of abnormal hemoglobins, among which are the methemoglobins, which have an abnormal affinity for O_2; (3) age- or disease-related differences in the percentage of structurally normal HbF, which has a high affinity for oxygen; and (4) changes in the microenvironment that alter the intracellular concentration of 2,3-diphosphoglycerate (2,3-DPG).[18] The oxyhemoglobin interaction also is complicated by the Bohr effect (at a lower pH, Hb binds O_2 with less affinity) independent of 2,3-DPG concentration. Patients with severe acidosis have low concentrations of 2,3-DPG, which results in an oxygen dissociation curve that shifts to the left. However, the in vivo curve may be normally placed because the Bohr effect counterbalances the reduction in red cell 2,3-DPG. If metabolic acidosis is rapidly corrected, the prompt rise in blood pH is reflected in a proportional increase in oxygen affinity (the Bohr effect). However, there is a lag of several hours before the red cell 2,3-DPG increases to normal. During this time, there is a shift to the left in both the in vivo and the in vitro O_2 dissociation curves. This phenomenon may compromise tissue oxygenation in patients who have diminished cardiovascular reserves.

Premature infants with respiratory failure may have a left-shifted O_2 affinity curve both because of the high levels of HbF and because of an acidosis-induced decrease in 2,3-DPG levels. Exchange transfusions with fresh adult blood have been found to reduce mortality, perhaps by providing blood with "normal" O_2 affinity.[19] Other reasons for impaired O_2 delivery are decreased RBC mass (anemia, which leads to a compensatory increase in 2,3-DPG) and decreased blood flow, either because of vascular anatomic abnormalities or because of increased blood viscosity (eg, in sickle cell disease). In addition to Hb-bound O_2, the oxygen dissolved in plasma (which normally amounts to less than 2% of the total oxygen carried in the blood) increases linearly with increases in PO_2. For this reason, very anemic patients, who have insufficient Hb with which to carry O_2, benefit from administration of O_2. Extensive research into the design of artificial blood has focused both on "red blood" (repackaged Hb from senescent RBCs or of Hb produced with genetic engineering) and "white blood" or perfluorocarbons (emulsions that dissolve large amounts of O_2), but their use is still limited and investigational. For now, RBC transfusions ameliorate anemia acutely, otherwise Epo may be used to elevate Hb over several weeks (see also Chapter 93). Although antibody-mediated Epo-associated pure red cell aplasia is infrequent,[20] familiarity with possible Epo toxicity should accompany its use.

Granulopoiesis

As shown in Fig. 88.2, in addition to BFU-E, CFU-S also gives rise to several other distinct cell populations. The best characterized of these are the CFU-GM (also known as *granulocyte macrophage progenitor cell,* which in turn generates both CFU-G [granulocyte colony-forming units] and CFU-M [monocyte-macrophage colony-forming units]) and the CFU-Eos (eosinophil colony-forming units). As with the CFU-E, these are not morphologically recognizable and probably masquerade in the bone marrow as small lymphocytes. They are identified on the basis of growth characteristics in in vitro bone marrow culture assays.

Subsequent stages of granulocytic (neutrophilic, eosinophilic, and basophilic) and

monocytic differentiation can be visualized by routine histochemical stains of bone marrow aspirates.[21] In the neutrophilic polymorphonuclear (PMN) series, the transition from myeloblast to mature PMN involves an overall decrease in cell size; coarsening, indentation, and ultimately separation of nuclear chromatin, with loss of nuclear chromatin, with loss of nucleoli; and replacement of azurophilic granules (whose contents include myeloperoxidase [MPO]), prominent in promyelocytes, by the specific granules (containing a number of secretory factors important for neutrophil function but not MPO) in mature PMNs. Other structural changes during the course of PMN maturation include the disappearance of certain surface antigens, which can be identified by specific monoclonal antibodies, and the appearance of receptor sites for complement (C3) and for the Fc portion of the immunoglobulin molecule. These stages in development are accompanied by functional changes, including increases in cell motility, responsiveness to chemoattractants, deformability, and phagocytic capabilities.

Parallel morphologic and functional changes occur with eosinophilic granulocyte differentiation. It is noteworthy that the peroxidase in eosinophil granules is different from that in neutrophils or monocytes so that congenital deficiencies of myeloperoxidase in the latter cells leave eosinophil function intact. The blood basophil (which histologically is similar to the tissue mast cell) also is presumed to arise in the bone marrow from the CFU-GM. In contrast to the CFU-Eos, there is no evidence as yet for a separate basophil CFU. DNA labeling studies have demonstrated the kinetics of neutrophil development within the bone marrow. As shown in Fig. 88.3, there is a mitotic pool (myeloblast and myelocyte) that allows for amplification of cell number and a storage or reserve pool (metamyelocyte and PMN) that in older children and adults contains roughly 100 times the number of granulocytes normally found in the peripheral blood.[22] This reserve is mobilized and leads to mature neutrophilia at times of stress (eg, sepsis, exercise, tachycardia, and pregnancy) or on administration of pharmacologic doses of corticosteroids or exposure to endotoxin. In neonates, the storage pool is only two to three times the circulating pool of PMNs and can be depleted, for example, by overwhelming sepsis.[23] Sepsis-related neutropenia may be due to apoptosis of neutrophils and their progenitors as well as a block in their maturation.[24] Thus, sepsis results in both neutropenia and neutrophilia.

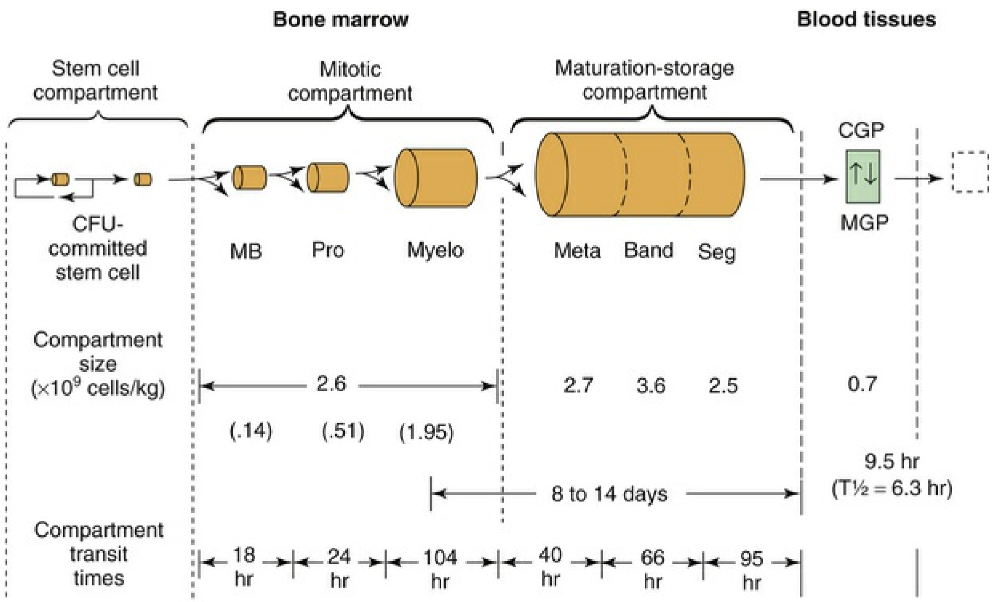

FIG. 88.3 Model of the production and kinetics of neutrophils in humans. The marrow and blood compartments have been drawn to show their relative sizes. The compartment transit times, as derived from $DF^{32}P$ studies, are shown on the next to last line. Values derived from tritiated thymidine studies are shown on the last line. (Modified from Wintrobe MN, et al. Clinical Hematology. ed 8. Philadelphia: Lea & Febiger; 1981.)

Eosinophilic granulocytes also have mitotic and storage pools in the marrow that are about 300 times that seen in the periphery. After less than a week, they are released from the marrow in response to hypoxia and eosinophilic factors (eg, heparin, histamine). In contrast to their effects on neutrophils, corticosteroids and epinephrine block mobilization of eosinophils from the marrow. The effect of epinephrine can be blocked by propranolol, suggesting mediation by β-adrenergic receptors. Little is known about basophil development in the bone marrow. Monocyte development, which, as previously suggested, is closely related to myelopoiesis, is also poorly understood. However, there does not appear to be a storage pool.

The mature neutrophil escapes from the marrow into the circulation by migration through reversible gaps between the endothelial cells lining the sinuses and capillaries. Factors known to influence this process include chemoattractants, such as products of the serum complement system. Those factors noted previously that mobilize the storage pool may cause an egress of less mature granulocytes with a resultant "shift to the left" in the peripheral blood. Once in the periphery, approximately half of the polymorphs adhere to the endothelium of blood vessels as the marginating pool while the other half actually circulate. Stress and epinephrine release the marginating cells and therefore double the absolute granulocyte count. Eosinophils have a similar arrangement of circulating and marginating cells, whereas the marginating pool of monocytes is three times that of the circulating pool.

The life span of the neutrophil once in the periphery may be as long as 5.4 days but can be hours in the presence of inflammation, fever, or infection. Neutrophils are irreversibly removed from the circulation into the liver, lungs, bowel, or bladder, back to the bone marrow, or to sites of infection where they contribute to the acute

inflammatory response. Their extravascular half-life also is on the order of hours. Although the circulating half-life of eosinophils is comparable with that of neutrophils, eosinophils can persist in the tissues for many days. Under pathologic conditions, eosinophils may cycle back and forth between the tissues and circulation.

Monocytes also have a circulating half-life measured in hours. Once in the tissues, however, they mature into macrophages. Their precise functions depend on the organ of residence; for example, in the liver they are identified as Kupffer cells and in the lung as alveolar macrophages. Macrophages may be "polarized" by cytokines or ligands for the toll-like receptors into two categories: either an antiinflammatory (M1) or a proinflammatory (M2) macrophage.

The CSFs that regulate myelopoiesis are diverse, and their biological specificities may overlap.[25] Cytokines such as interleukin (IL)-1, tumor necrosis factor, granulocyte-macrophage colony-stimulating factor (GM-CSF), and G-CSF expand the PMN precursor compartment and mobilize them by promoting their diapedesis from the marrow and from vascular endothelium. Endotoxin promotes the host inflammatory response by stimulating endothelial cells, macrophages, and fibroblasts to produce cytokines.

Both GM-CSF and G-CSF prime PMNs for enhanced phagocytosis and superoxide production in vitro, modulate cell surface expression of adhesion receptors, inhibit apoptosis, and promote antibody-dependent cellular cytotoxicity. However, GM-CSF inhibits chemotaxis, whereas G-CSF promotes it. G-CSF acts only on the granulocytic lineage. GM-CSF affects macrophages and eosinophils, which accounts for its side effects of eosinophilia and, at high doses, capillary leak syndrome. Because of stickiness and margination along vascular endothelium, a transient drop in O_2 saturation may occur within minutes after administration. GM-CSF can result in transient fever. Bone pain may occur with administration of either drug, if marrow production is high. WBCs must be monitored, and the drug typically is discontinued when the absolute neutrophil count exceeds 1500 /μL. When it is discontinued, the number of circulating PMNs decreases. Multiple trials have demonstrated the efficacy of growth factors in decreasing the time interval of profound neutropenia or length of antibiotic coverage and hospitalization; however, their use has not changed overall survival. Clinical uses of G-CSF and GM-CSF are summarized in Table 88.3. Although nonhematopoietic tumor cell lines can display receptors for GM-CSF or G-CSF, administration of these drugs has not led to an appreciated increase in relapse or progressive disease. There has been concern that erythroid stimulating agents might stimulate cancer growth.[26] These agents can be given to patients with myeloid leukemias or myelodysplastic syndromes without adverse effects. Based on *adult* studies, the FDA now warns that erythropoiesis stimulating agents may lead to serious cardiovascular and stroke events when Hgb is greater than 11 g/dL and may lead to tumor progression and decreased survival.

TABLE 88.3

Comparison of Granulocyte-Macrophage Colony-Stimulating Factor and Granulocyte Colony-Stimulating Factor

Factor	Additional Uses	Starting Dose
G-CSF	Chemotherapy-induced suppression, severe congenital neutropenia, peripheral stem cell harvest, drug-induced neutropenia	5 μg/kg/d SQ or IV
GM-	Autologous SCT, enhanced antigen presentation, drug-induced neutropenia	250 μg/m^2/d SQ

CSF		or IV

SCT, stem cell transplantation.

As in the case of RBC and platelet development, normal myelopoiesis also requires the presence of vitamin and mineral growth factors. One hallmark of megaloblastic anemia (vitamin B_{12} and folate deficiencies) is the hypersegmented PMN. The hypochromic microcytic anemia of copper deficiency is characteristically associated with neutropenia. Among the nonlymphoid WBCs, clinical sequelae of quantitative or qualitative deficiencies of neutrophils have been particularly well studied. Systemic or mucocutaneous bacterial infections (gram-positive and gram-negative organisms) are frequent. They occur with an incidence that increases with the degree and duration of neutropenia and in the presence of indwelling catheters, intravascular lines, and endotracheal tubes.

Recommendations for prevention of infections in neutropenia include strict handwashing, changing sites of percutaneous lines as often as every 48 hours, and use of recombinant CSFs in limited situations (as noted previously). The use of prophylactic antibiotics and reverse isolation is controversial and will vary among centers and divisions within centers. In addition to clearing bacteria and fungi, monocytes secrete a variety of inflammatory cytokines.

Megakaryocyte and Platelet Production

The CFU-S gives rise to a committed megakaryocyte progenitor, the CFU-Mega (see Fig. 88.2) identifiable in in vitro clonogenic assays and by the presence of platelet glycoprotein surface antigens. Unlike RBC and granulocyte differentiation in which cell division keeps up with mitosis, the next phase of development of megakaryocytes is characterized by endoreduplication, a process of mitosis without cell division that leads to increased DNA content up to a ploidy of 32N (where 2N is a diploid cell). With increasing ploidy comes increased cell volume, degree of nuclear lobulation, and granules containing factors that influence platelet function. A system of “demarcation membranes” identified by electron microscopy separates the megakaryocyte cytoplasm into several thousand anucleate platelets, which are shed into the lumens of the marrow sinusoids. The entire process takes about 5 days. Although megakaryocytes can be visualized on bone marrow aspirates and biopsy specimens, their quantitation by these techniques is approximate and correlates only loosely with platelet production. Factors controlling platelet shedding have not been studied extensively. With exceptions, however, large platelets or megathrombocytes (increased mean platelet volume) are seen in thrombocytopenia caused by increased platelet destruction. Normal platelet volume occurs more frequently in thrombocytopenia resulting from decreased platelet production.

Some platelets move directly from the marrow to the blood, where they remain; others go temporarily to the spleen, which possibly contributes to their further maturation. Normally one-third of the total body platelet mass is sequestered there, although the number can go as high as 90% in pathologic states. Once in the peripheral blood, platelets have a life span of about 10 days. Chromium studies, useful to assess platelet life span, have severe limitations in estimating the extent of organ-specific uptake of platelets and response to splenectomy.

Thrombopoietin (TPO) is the critical growth factor for the production of platelets.[27] Whereas IL-3, GM-CSF, Epo, IL-11, and IL-6 stimulate CFU-Mega growth in vitro,

none of these factors has proved to be highly effective in increasing platelet counts in clinical trials. Instead, there are two FDA-approved thrombopoietin receptor activators, romiplostim and eltrombopag. TPO potently stimulates the expression of CFU-Mega and megakaryocytes, resulting in an increased platelet mass. Because knockout mice have been created that lack the gene for the thrombopoietin receptor but still produce some platelets, other cytokines must contribute to platelet production. These factors, such as IL-3 and IL-11, most likely synergize with thrombopoietin. Although iron deficiency anemia is often associated with thrombocytosis, increases in Epo may not be the immediate mechanism, and not all disease states associated with elevated Epo levels are characterized by increased platelet number. As with the other cell lines, megakaryopoiesis is also dependent on vitamins; severe megaloblastic anemia may be associated with thrombocytopenia and bizarre platelet and megakaryocyte morphology.

Spontaneous bleeding is unlikely unless there are fewer than 20,000/μL normally functioning platelets. However, for major invasive procedures such as surgery or placement of arterial lines or endotracheal tubes, the platelet count should be maintained at a level more than 50,000/μL or even 100,000/μL. The minimum platelet count for performing a spinal tap is less clear, but most clinicians would ask that the platelet count be at least 30,000/μL. Other indications for platelet transfusions are discussed in Chapter 93. In the rare patient with idiopathic thrombocytopenic purpura and intracranial hemorrhage, optimum control of bleeding requires cooperation among neurosurgery, general surgery, hematology, and intensive care clinicians and some combination of splenectomy, high-dose gamma globulin, steroid therapy, and platelet transfusions.

Lymphopoiesis

The bone marrow and thymus are the primary lymphoid organs, the site of lymphocyte production. The secondary lymphoid organs, to which the B and T cells migrate, include the spleen, lymph nodes, and gut-associated lymphoid tissue (tonsils, appendix, and Peyer patches of the small intestine).

Spleen

The spleen is enclosed in a thick, fibromuscular capsule. Numerous trabeculae spring from the capsule to divide the interior pulp into lobules, within which is a scaffolding of reticular cells and fibers. Unlike the thymus, the spleen has a hilum through which the splenic artery and its branches enter and then branch further to course along the trabeculae. Collaterals from the gastric artery enter through the splenic capsule so that splenic artery ligation does not result in infarction. The branches of the splenic artery pass into the parenchyma to form central arteries that are surrounded for much of their length by a dense sheath of T lymphocytes and macrophages. Lymphoid follicles, some with germinal centers containing B cells from the bone narrow (as noted previously), are also present in the periarterial lymphatic sheath. Together the B-cell– and T-cell–dependent areas compose the white pulp of the spleen. The rest of the splenic parenchyma is the red pulp. It contains radial branches of the central arteries that carry hemoconcentrated blood (plasma is skimmed off and runs in other arterial branches), well-defined endothelial

lined venous sinuses that ultimately drain into the splenic vein, and an anatomically separate reticulin network, the splenic vein, which functions as endothelial-lined blood vessels. Most of the circulation runs from the arterial system into the cords and then into the venous system, probably by squeezing through gaps in the endothelium. After the neonatal period, a marginal zone of the red pulp that abuts the white pulp becomes more prominent. It contains antigen-processing macrophages that are needed for B-cell function. It is believed to be the initial site of interactions between antigen and lymphocytes. Small numbers of efferent lymphatic vessels lie at the proximal end of the central arteries and leave the spleen through the trabeculae.

Normally the spleen is found in the left-upper quadrant of the abdomen. Its weight increases linearly with body weight until puberty, after which it shrinks somewhat. A spleen tip is palpable in 10% of normal children. On the basis of data from splenectomy cases, small accessory spleens occur in almost 20% of individuals. Generally they are located near the hilum of the main spleen, with which they share their vascular supply.

The spleen has many functions. The red pulp filters damaged and old RBCs from the systemic circulation by several mechanisms: (1) The cells are distorted and disrupt as they pass through the small lumens of the arterial capillaries or between the endothelial cells of the sinuses: In particular, cells with HbS undergo increased sickling, and cells with abnormalities of glycolytic metabolism or senescent cells become increasingly fragile in the face of decreased O_2 tension with lactic acidosis and decreased adenosine triphosphate production. (2) Cells are entrapped in the viscous blood within the fine mesh reticulin. (3) Cells undergo antibody-mediated (especially immunoglobulin G) hemolysis or phagocytosis, as seen in some autoimmune hemolytic anemias. Damaged cells or their debris produced by any of these mechanisms are removed by macrophages of the red pulp or may escape back into the circulation. Rigid inclusions such as Howell-Jolly bodies may be pitted without destroying the parent RBC on passage through the sinus endothelium. Therefore the presence of even small numbers of Howell-Jolly bodies is a subtle indicator of impaired splenic function except in the term and especially in the premature neonate, where they also are seen and thought to be a normal developmental stage.

As mentioned earlier, the spleen also is a temporary reservoir for platelets and to a small extent for WBCs. Thus after splenectomy there is a usually transient thrombocytosis that resolves within 3 to 6 months. In children it does not appear to carry a predisposition to thrombosis even with platelet counts as high as $10^9/\mu L$. In the presence of antiplatelet or anti-WBC antibody (some synthesized by the spleen) and in hypersplenism without antibody, the spleen may also function as a filter and result in thrombopenia and neutropenia, which may be reversible by surgical or pharmacologic (steroids, high-dose gamma globulin) splenectomy (see the “Megakaryocyte and Platelet Production” section).

The spleen, predominantly the white pulp and marginal zone, also plays a number of roles in host defense, elegantly and elaborately discussed elsewhere.[15] In short, splenectomy has been associated with an increased incidence of serious infections with encapsulated bacteria, intraerythrocytic parasites, and possibly leukemia in patients who have splenectomy as part of the management of Hodgkin disease. Most clinicians recommend use of *Haemophilus influenzae* type b, meningococcal, and

pneumococcal vaccines 1 to 3 weeks before splenectomy (in previously unimmunized individuals), with boosters against pneumococcal disease every 5 to 10 years, and prophylactic antibiotics for variable times but at least through adolescence. Although it is not a site of hematopoiesis beyond fetal life under normal conditions, in certain disease states the spleen can reactivate its hematopoietic potential. These states include some congenital hemolytic anemias and acquired diseases, such as myeloid metaplasia. All are associated with splenomegaly and usually with hepatomegaly, signifying a more general expansion of hematopoiesis. The liver can fulfill some of these functions so that in functionally or literally asplenic patients RBC life span, for example, is not increased. However, the liver is less effective at other functions, including pitting and host defense.

Lymph Nodes

Like most of the rest of the lymphoreticular system, lymph nodes are surrounded by capsules and have architecturally distinct cortices and medullary zones, functionally distinct B-cell– and T-cell–dependent areas, and macrophages—all compartmentalized by a reticular meshwork. Many of the small lymphocytes, especially the T cells, continually are recycled through the systemic circulation by the thoracic duct. They function primarily as a site of interaction between the immune system and invading antigens. Mediastinal lymph node enlargement as a result of invasion by lymphoid or nonlymphoid tumors or from endogenous antigenic stimulation may compromise the airway and present anesthetic risks.

CHAPTER 89

Erythron in Critical Illness

Ahmed Said, Stephen Rogers, Allan Doctor

PEARLS

- Together, all red blood cells (RBCs) at each stage of development may be considered an organ (termed the *erythron*) now appreciated to participate in active regulation of regional blood flow distribution as well as O_2 and CO_2 transport.
- RBCs are subject to intense biochemical, biomechanical, and physiologic stress during repeated circulatory transit; as such, they possess unique properties and robust energetic and antioxidant systems to maintain functionality for a 3- to 4-month lifetime.
- RBCs actively regulate blood flow and distribution to maintain coupling between O_2 delivery and demand. The trapping, processing, and delivery of nitric oxide by RBCs have emerged as a conserved mechanism through which regional blood flow is linked to biochemical cues of perfusion sufficiency.
- A new paradigm for O_2 delivery homeostasis has emerged, based on coordinated gas transport and vascular signaling by RBCs. By coordinating vascular signaling in a fashion that links O_2 and nitric oxide flux, RBCs couple vessel caliber (and thus blood flow) to O_2 need in tissue. Malfunction of this signaling system is implicated in a wide array of pathophysiologies and may be, in part, explanatory for the dysoxia frequently encountered in the critical care setting.

Introduction

The erythron includes red blood cells (RBCs) at all stages of development, from progenitors to senescent forms, and is the organ (composed of anucleated cells in suspension) responsible for oxygen (O_2) transport from lungs to tissue.[1] This role is newly appreciated to include active vasoregulation (by RBCs) that links regional blood flow to O_2 availability in the lung and to consumption in the periphery.[2] Considerable energy is devoted to maintaining a robust RBC population (20 trillion to 30 trillion cells circulate in the average adult, and approximately 25% of the cells in the body are RBCs); 1.4 million RBCs are released into the circulation per second, replacing ~1% of the circulating mass per day. Mature RBCs have a life span of ~4

months, the majority of which is spent traversing the microcirculation. It is estimated that an RBC travels approximately 400 km during this interval, having made 170,000 circuits through the vascular tree. Circulating RBCs demonstrate unique physiology and are adapted to withstand significant biomechanical and biochemical stress. As RBCs age, energy and antioxidant systems fail; key proteins (including hemoglobin [Hb] and lipids) suffer oxidative injury, negatively impacting performance (rheology, adhesion, gas transport, vascular signaling). Such cells acquire marks of senescence and are cleared by the spleen or by undergoing eryptosis (a process unique to RBCs, similar to apoptosis). Of importance, this process may be accelerated in the course of critical illness and thereby, by limiting O_2 delivery, influence organ failure progression and outcome.

Moreover, it is essential to note that in the setting of insufficient O_2 delivery, blood flow (rather than content) is the focus of O_2 delivery regulation: O_2 content is relatively fixed, whereas flow can be increased by several orders of magnitude. Thus, blood flow volume and distribution are actively regulated to maintain coupling between O_2 delivery and demand. The trapping, processing, and delivery of nitric oxide (NO) by RBCs have emerged as a conserved mechanism through which regional blood flow is linked to biochemical cues of perfusion sufficiency. This chapter reviews conventional RBC physiology influencing O_2 delivery (O_2 affinity and rheology) and introduces a new paradigm for O_2 delivery homeostasis based on coordinated gas transport and vascular signaling by RBCs. By coordinating vascular signaling in a fashion that links O_2 and NO flux, RBCs couple vessel caliber (and thus blood flow) to O_2 need in tissue. Malfunction of this signaling system is implicated in a wide array of pathophysiologies and may in part explain the dysoxia frequently encountered in the critical care setting.

Oxygen Transport

Hemoglobin (Hb) is formed by 2 α and 2 β globin chains, each carrying a heme prosthetic group composed of a porphyrin ring bearing a ferrous atom that can reversibly bind an oxygen (O_2) molecule. In the deoxygenated state, the Hb tetramer is electrostatically held in a tense (T) conformation. Binding of the first O_2 molecule leads to mechanical disruption of these bonds, an increase in free energy, and transition to the relaxed (R) conformation. Each successive O_2 captured by T-state Hb shifts the Hb tetramer closer to the R state, which has an estimated 500-fold increase in O_2 affinity. This concept of thermodynamically coupled "cooperativity" in O_2 binding was first described by Perutz and explains the sigmoidal appearance of the O_2-Hb binding curve, also known as the oxy-hemoglobin dissociation curve (ODC) (Fig. 89.1). Moreover, understanding of allosteric influence of protein function by "heterotropic effectors" was first achieved following description of the variation in Hb~O_2 affinity. For example, for Hb~$O_{2,}$ which binds to the heme "active" site, is the homotropic ligand, and all other molecules influencing the Hb~O_2 binding relationship are termed *heterotropic effectors.* In addition to the homotropic effects of ligand binding on quaternary conformational changes (eg, cooperativity), primary ligand binding affinity (O_2) is also affected by multiple heterotropic effectors of

significant physiologic relevance (also known as allosteric effectors). The major heterotropic effectors that influence Hb O_2 affinity are hydrogen ion (H^+), chloride ion (Cl^-), carbon dioxide (CO_2), and 2,3-diphosphoglycerate (DPG).

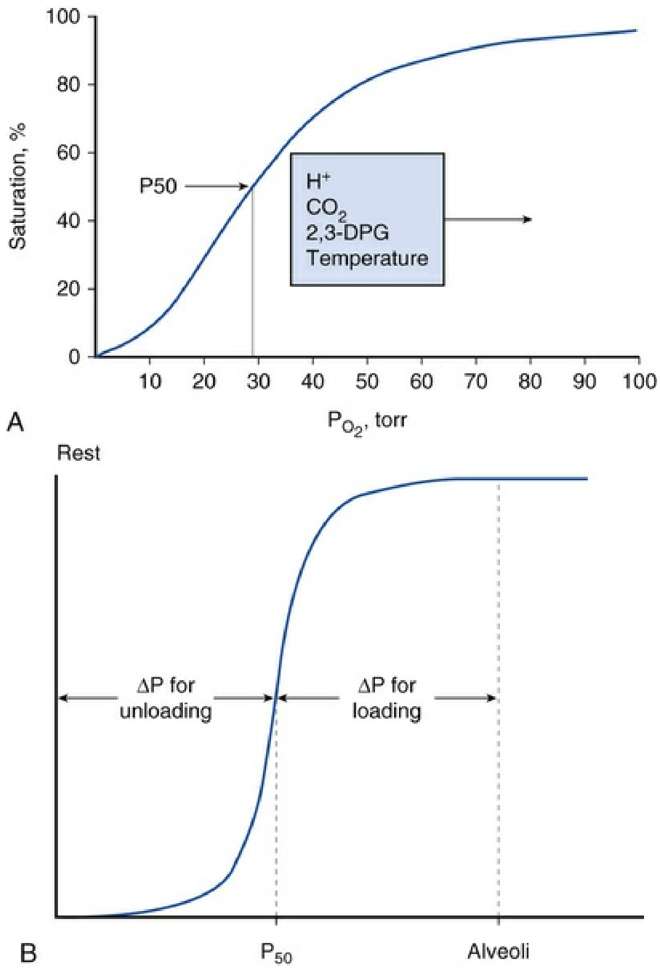

FIG. 89.1 **Oxyhemoglobin Dissociation Curve. (A) The normal whole blood oxygen dissociation curve (ODC). P_{50} is the PO_2 at which hemoglobin is half-saturated with O_2. The principal effectors that alter the position and shape of the curve under physiologic conditions are indicated. (B) Changes in P_{50} optimize O_2 loading in the lungs and unloading in tissue. The difference in O_2 tension (ΔP) between the alveolar air and the pulmonary-capillary blood provides the gradient for loading in the lungs. The difference in O_2 tension between the blood leaving the lungs and perfusing tissue provides the gradient for O_2 unloading in the periphery. Optimal O_2 transport is achieved through P_{50} shifts that match the gradients for loading and unloading to the respective diffusing capacities of the lungs and tissues.** (A, Adapted from Winslow RM. The role of hemoglobin oxygen affinity in oxygen transport at high altitude. Respir Physiol Neurobiol. 2007;158:121-127; B, Adapted from Hsia CCW. Respiratory function of hemoglobin. N Engl J Med. 1998;338 : 239-247.)

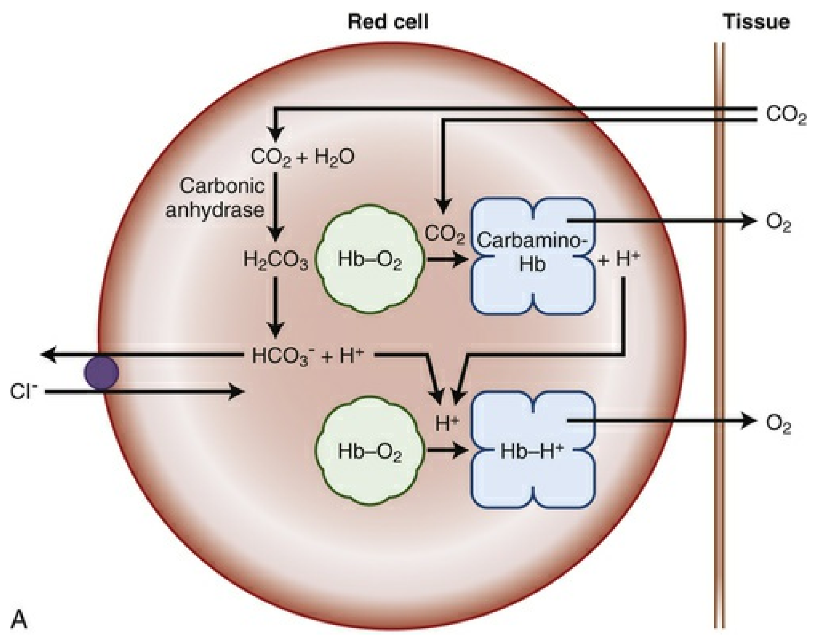
P_{50}, the oxygen tension at which 50% of Hb binding sites are saturated, is the standard metric employed to quantify change in Hb~O_2 affinity and is inversely related to the binding affinity of Hb for O_2.[3,4] Elevated levels of H^+, Cl^-, and CO_2 reduce O_2 binding affinity (eg, raise P_{50}). This allosteric shift in O_2 affinity, called the Bohr effect, arises from the interactions among the above heterotropic effectors bound to different sites on hemoglobin, all of which serve to stabilize the low-energy, low-affinity, T-state Hb conformation. This effect is achieved by complex interactions between carbonic anhydrase (CA) and the anion exchange protein 1

(AE1) (also known as the Band 3 [B3] membrane protein) (Fig. 89.2). Specifically, CA generates H^+ and HCO_3^- from CO_2 encountered in the microcirculation; HCO_3^- then exchanges for Cl^- across the RBC membrane through AE1. As a consequence, extra erythrocytic CO_2 is converted into intraerythrocytic HCl by the CA-AE1 complex, thus acidifying RBC cytoplasm and raising P_{50} (lowering affinity, also termed *right shifting* the ODC). Additionally, through the Haldane effect, CO_2 more directly lowers O_2 affinity (by binding to the *N*-terminus of the globin chains to form a carbamino, further stabilizing T-state Hb); carbamino formation also releases another hydrogen ion (further reinforcing the *right shift* in ODC) (see Fig. 89.2). This set of reactions is reversed in the alkaline (and low CO_2) milieu in the pulmonary circulation, leading to increased Hb~O_2 binding affinity (lower P_{50}). In sum, this physiology vastly improves O_2 transport efficiency by enhancing gas capture in the lung and release to tissue, and it does so in proportion to perfusion sufficiency (in the setting of impaired perfusion, acidosis and hypercapnea improve O_2 release). In the setting of impaired O_2 delivery that results in anaerobic glycolysis, lactate diffusion into capillary blood (by lowering pH) further increases O_2 dissociation and facilitates O_2 delivery. Of note, this tightly regulated modulation of O_2 affinity requires coordinated interaction of a complex intraerythrocytic protein network and may fail consequent to acquired RBC injury in the setting of critical illness,[5-8] thereby partially explaining the dysoxia commonly observed in this setting.



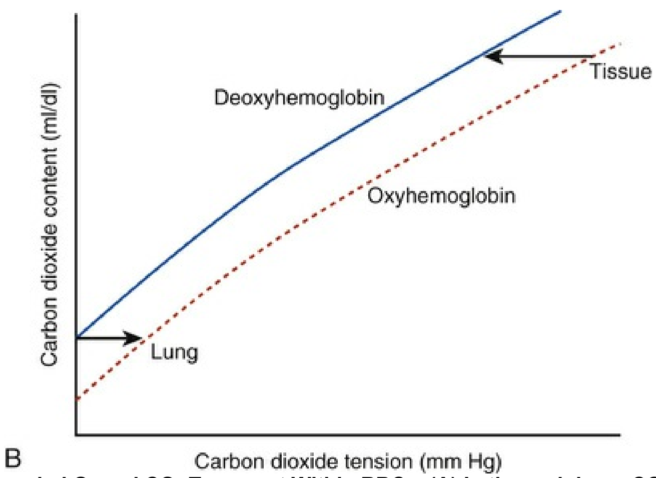


FIG. 89.2 **Coupled O_2 and CO_2 Transport Within RBCs. (A) In the periphery, CO_2 uptake by RBCs, processing by the carbonic anhydrase system (Bohr effect), and carbamino-Hb formation (Haldane effect) stabilize T conformation and facilitate O_2 release. (B) Binding of O_2 to Hb reduces binding affinity for CO_2, leading to a rightward shift of the CO_2 dissociation curve and facilitating CO_2 release in the lung. This interaction reverses upon deoxygenation in the periphery tissues, facilitating CO_2 uptake and minimizing the arteriovenous CO_2 difference.** (Adapted from Hsia CCW. Respiratory function of hemoglobin. N Engl J Med. 1998;338:239-247.)

Less acute modulation of P_{50} is achieved by DPG, a glycolytic intermediate that binds in an electrically charged pocket between the β chains of hemoglobin, which stabilizes the T conformation, decreasing O_2 affinity and elevating P_{50}. DPG binding also releases protons, lowering intracellular pH and further reinforcing the Bohr effect. DPG in RBCs increases whenever O_2 availability is diminished (as in hypoxia or anemia) or when glycolytic flux is stimulated. Lastly, temperature significantly influences Hb~O_2 affinity. As body temperature increases, affinity lessens (P_{50} increases, ODC shifts right); the reverse happens in hypothermia. This feature is of physiologic importance during heavy exercise, fever, or induced hypothermia. It should be noted that clinical co-oximetry results and blood gas values are reported at 37°C and not at true in vivo temperature and can lead to either under- or overestimation of true $HbSO_2$% values and blood O_2 tension.

Carbon Dioxide Transport

As a lipophilic molecule, carbon dioxide (CO_2) produced from tissue respiration readily diffuses into capillary blood and through the RBC membrane.[9] A minority (5%-10%) of diffused CO_2 binds to the α-amino terminus of Hb globin chains as carbaminohemoglobin, lowering O_2 affinity (raising P_{50}); this P_{50} shift is termed *the Haldane effect*.[9,10] The majority of the CO_2 is hydrated by the two intraerythrocytic carbonic anhydrase (CA) isoforms, CA I (low turnover rate) and CA II (high turnover rate); this conversion into bicarbonate (and a proton, as discussed earlier) is essential for efficient CO_2 transport and for maintaining the venous-arterial difference in total CO_2 (see Fig. 89.2). The released protons stabilize the T conformation of hemoglobin and thereby facilitate O_2 offloading in proportion to CO_2 genesis (and thus, regional tissue respiration). Carbaminohemoglobin also acts to directly stabilize T-state conformation. The process reverses during pulmonary

transit (because the lungs act as a CO_2 sink), raising intraerythrocytic pH and enhancing O_2 affinity in proportion to regional alveolar ventilation (CO_2 removal).

Biophysical Factors Influencing Gas Transport

Blood Rheology

Disease-based variation in blood fluidity has been recognized since the early 20th century,[11] and there is substantive evidence that this property strongly influences tissue perfusion.[12] Plasma is a newtonian fluid (viscosity is independent of shear rate); its viscosity is closely related to protein content and in critical illness, physiologically significant changes in viscosity may vary with concentration of acute phase reactants.[13-15] Whole blood, however, is considered a non-newtonian suspension (fluidity cannot be described by a single viscosity value); whole blood fluidity is determined by combined rheologic properties of plasma and the cellular components.

The cellular components of blood, particularly RBCs, influence blood viscosity as a function of both number and deformability. RBC concentration in plasma (hematocrit) has an exponential relationship with viscosity and meaningfully diminishes tissue perfusion when Hct exceeds ~60 to 65. RBC deformability, or behavior under shear stress, also strongly influences blood fluidity. Normal RBCs behave like fluid drops under most conditions, are highly deformable under shear, and orient with flow streamlines. However, during inflammatory stress, RBCs tend to aggregate into linear arrays like a stack of coins (rouleaux); fibrinogen and other acute phase reactants in plasma stabilize such aggregates, significantly increasing blood viscosity. Such a change in viscosity most impacts O_2 delivery during low-flow (eg, low-shear) states (such as in critical illness) in the microcirculation.[16] RBC biomechanics and aggregation impact blood viscosity, strongly influencing the volume and distribution of O_2 delivery (again, more so in the low-shear microcirculation or when vessel tone is abnormal).[17] This hemorheologic physiology is perturbed by oxidative stress (common in critical illness)[18,19] and in sepsis.[20-25] This has been attributed to increased intracellular 2,3-DPG concentration,[26] intracellular free Ca^{2+},[27] and decreased intraerythrocytic ATP with subsequent decreased sialic acid content in RBC membranes.[28] Both increased direct contact between RBCs and WBCs and reactive oxygen species released during sepsis have also been shown to alter RBC membrane properties.[29,30]

Red Blood Cell Aggregation and Adhesion

As noted previously, in the absence of shear, RBCs suspended in autologous plasma stack in large aggregates, known as rouleaux. Acute phase reactants, especially fibrinogen, C-reactive protein, serum amyloid A, haptoglobin, and ceruloplasmin, have been shown to increase RBC aggregation.[31] Pathophysiologic conditions such as sepsis and ischemia-reperfusion injury have been shown to alter RBC surface proteins and increase RBC "aggregability."[19] Activated white blood cells (WBCs) are also thought to cause structural changes in the RBC glycocalyx and increase RBC aggregability.[32]

Under normal conditions, RBC adherence to endothelial cells (ECs) is insignificant, and RBC deformability permits efficient passage through the microcirculation. Again, under normal conditions, enhanced EC adherence plays a role in the removal of senescent RBCs in the spleen. However, during critical illness, RBC~endothelial interactions are altered by RBC injuries associated with sepsis[22,23,33,34] or oxidative stress.[19] This is more prominent with "activated" endothelium, as frequently occurs in critical illness.[34-36] Such RBC~endothelial aggregates create a physiologically significant increase in apparent blood viscosity.[17] Moreover, RBC adhesion directly damages endothelium[37-40] and augments leukocyte adhesion,[41-44] further impairing apparent viscosity and microcirculatory flow. This phenomenon is commonly appreciated in the pathophysiology of vasoocclusive crises in sickle cell disease patients, malaria, diabetic vasculopathy, polycythemia vera, and central retinal vein thrombosis, but it may be more widespread than originally appreciated.

Red Blood Cell Deformability

Tissue deformation can be defined as the relative displacement of specific points within a cell or structure. Mature RBCs are biconcave disks ranging from 2 to 8 μm in thickness, which act like droplets that deform reversibly under the shear encountered during circulatory transit.[17,45] Unique RBC geometry and deformability arises from (1) cytoplasmic viscosity and (2) specific interactions between the plasma membrane and underlying protein skeleton[28] (Fig. 89.3). Cytoplasmic viscosity is mainly determined by hemoglobin concentration, which varies with intraerythrocytic hydration, which is actively regulated by ATP-dependent cation pumps.[46] The integral transmembrane membrane proteins AE-1 (also known as B3) and glycophorins are reversibly anchored to a submembrane filamentous protein mesh composed of spectrin, actin, and protein 4.1. The linear extensibility of this mesh defines the limits of RBC deformability.[47] Maintenance of membrane-mesh interactions and robust RBC mechanical behavior is dependent on ATP-dependent ion pumps as well as support from NADPH-dependent antioxidant systems.[46] The sole energy source (for both) in RBCs is anaerobic glycolysis, which is discussed in detail later. RBC geometric and mechanical alterations secondary to impaired metabolism (leading to RBC dehydration, elevated intraerythrocytic calcium, and ATP/NADPH depletion) are well-described consequences in blood stored for prolonged periods[48] and in RBCs subjected to significant metabolic stress during critical illness.[49,50]

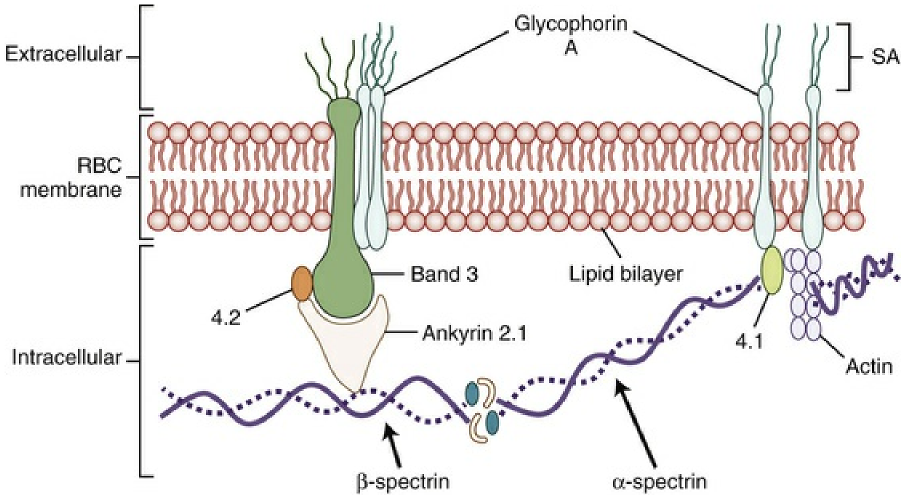

FIG. 89.3 Schematic Representation of RBC Membrane. The membrane is composed of a phospholipid membrane bilayer and transmembrane proteins including glycophorin A and Band 3 proteins. Glycophorin A is the major sialoglycoprotein of the RBC. Sialic acid (SA) bound to glycophorin A is responsible for the negative charge of the RBC membrane. The intracellular compartment (IC) is constituted by spectrin (α and β subunits), actin, protein 4.1, and ankyrin. (Adapted from Piagnerelli M, et al. Red blood cell rheology in sepsis. Intensive Care Med. 2003; 29(7):1052-1061.)

Regulation of Blood Flow Distribution by Red Blood Cells

Microcirculatory blood flow is physiologically regulated to instantaneously match O_2 delivery to metabolic demand. This extraordinarily sensitive programmed response to tissue hypoperfusion is termed *hypoxic vasodilation (HVD)*.[51] This process involves the detection of point-to-point variations in arteriolar O_2 content[52] with the subsequent initiation of signaling mechanism(s) capable of immediate, regionally specific, modulation of vascular tone (Fig. 89.4).

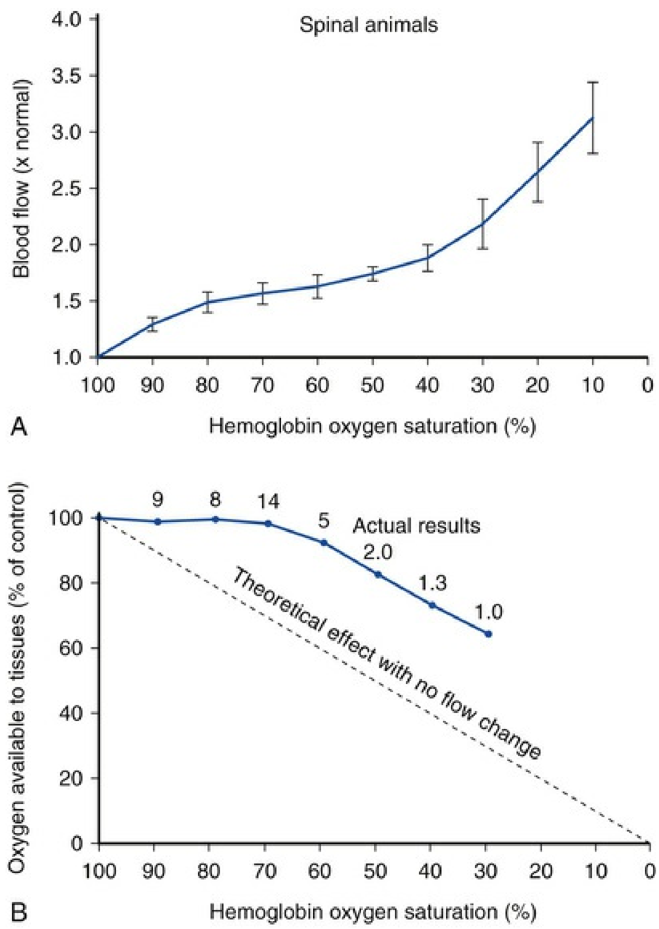

FIG. 89.4 Local vascular reflexes support maintenance of O_2 delivery to tissue in the setting of progressive hypoxia. In a classic paper (51), Guyton demonstrated regional autoregulation of systemic blood flow in normal dogs (following spinal anesthesia) by observing variation in blood flow during constant pressure blood perfusion of the femoral artery, while reducing the hemoglobin oxygen saturation (Hb SO_2%) from 100% to 0% in the perfusing blood. (A) Stepwise reduction in Hb SO_2% caused a progressive increase in blood flow through the leg. (B) These data demonstrate that autoregulation of blood flow occurs at a local level and this regulation serves to improve oxygen supply when blood oxygen content falls. In addition, effects on blood flow were replicated by injecting partially deoxygenated versus oxygenated red blood cells into the artery, demonstrating that effects could be elicited during arteriovenous transit (<1 s).

In the 1980s, intracellular RBC Hb was identified as a potential circulating O_2 sensor, following demonstration that in severe hypoxia, O_2 content was more important than partial pressure of O_2 (PO_2) in the maintenance of regional O_2 supply.[53] It was later demonstrated in vivo that Hb O_2 saturation ($HbSO_2$) directly correlated with blood flow in a fashion independent of plasma or tissue PO_2.[54] These findings implicated a role for RBCs in the regulation of O_2 supply, given the following evidence: (1) the Hb molecule within the RBC is the only component in the O_2 transport pathway directly influenced by O_2 content, and (2) the level of O_2 content of the RBC at a particular point in the circulation is linked to the level of O_2

utilization.[55]

With the vascular O_2 sensor identified, the mechanism involved in mediating the vasoactive response has remained in debate. To date, three $HbSO_2$-dependent RBC-derived signaling mechanisms have been proposed, the first two linked to the vasoactive effector NO and the third to RBC adenosine triphosphate (ATP): (1) formation and export of S-nitrosothiols, "catalyzed" by Hb (SNOHb hypothesis)[56-58]; (2) reduction of nitrite (NO_2^-) to NO by deoxygenated Hb (nitrite hypothesis)[59]; and (3) hypoxia responsive release of ATP (ATP hypothesis).[55,60] Each of these hypotheses will be addressed further.

Role of Red Blood Cell–Nitric Oxide Interactions in Vasoregulation

Interest in the free radical NO began with its identification as endothelium-derived relaxing factor (EDRF), first reported in 1980,[61] which resolved the apparent paradox as to why acetylcholine, an agent known to be a vasodilator in vivo, often caused vasoconstriction in vitro. Experiments performed with dissected segments of rabbit thoracic aorta mounted on a force transducer demonstrated that handling of the tissue in a fashion that preserved endothelium always resulted in acetylcholine having relaxant properties. However, removal of the endothelium eradicated this action.[61,62] Identification of EDRF consequently led to a race to discover its chemical identity. It was not until 7 years later that two groups simultaneously published definitive studies characterizing and identifying EDRF as NO.[63,64] However, the means by which NO exerted its physiologic effects remained unknown, and effort focused upon identifying the "NO receptor(s)." This effort characterized the "classical" signaling pathway for NO via soluble guanylate cyclase (sGC) and cyclic guanosine 3′,5′-monophosphate (cGMP) that appeared to clarify the means by which NO achieves its myriad effects.[65] Over time, however, we now appreciate that this pathway has little to do with the vasoregulation that governs regional blood flow distribution.

In terms of the HVD response (which underlies blood flow regulation) it is essential to appreciate that endothelium-derived NO plays no direct role in this reflex.[54,66] Because of the O_2 substrate limitation, NO production by eNOS is most likely attenuated by hypoxia.[67,68] In fact, NO derived from eNOS[56] (and perhaps other NOS isoforms[69] or nitrite[70]) is taken up by RBCs, transported, and subsequently dispensed in proportion to regional O_2 gradients to effect HVD at a time and place remote from the original site of NO synthesis. This key process enables RBCs to instantaneously modulate vascular tone in concert with cues of perfusion insufficiency, including hypoxia, hypercarbia, and acidosis.[56,57]

Metabolism of Endothelium-Derived Nitric Oxide by Red Blood Cells: Historical View

In the original NO paradigm, NO derived from endothelial nitric oxide synthase (eNOS) was felt to play a purely paracrine role in the circulation, acting within the vicinity of its release.[71] Its metabolic fate was explained by the diffusion of the "gas" in solution and its terminal reactions (1) in vascular smooth muscle cells with the

ferrous heme iron (Fe^{2+}) of soluble guanylate cyclase (sGC)[72] and (2) in the vessel lumen, with the heme group (Fe^{2+}) of oxyHb (the resultant oxidation reaction forming MetHb and nitrate), or deoxyHb (the resultant addition reaction forming iron nitrosyl Hb; HbNO), or in plasma with dissolved O_2 (the resultant autoxidation reaction),[73] or O_2-derived free radicals including superoxide (O_2^-), hydrogen peroxide (H_2O_2), or hydroxyl radicals (OH^-). Several "barriers" were presumed to retard NO diffusing into the blood vessel lumen to react avidly with the abundance of Hb, including the RBC membrane, the submembrane protein matrix, and an unstirred layer around the RBC,[74,75] in addition to laminar blood flow.[76] These barriers were thought to limit these luminal reactions, thus allowing the local concentration of NO adjacent to endothelial cells to increase sufficiently to provide a diffusional gradient for NO to activate the underlying vascular smooth muscle sGC. Reactions of NO in the bloodstream were assumed only to scavenge/inactivate NO via the formation of metabolites unable to activate sGC.[72]

Metabolism of Endothelium-Derived Nitric Oxide by Red Blood Cells: Modern View

A much broader biological chemistry of endothelial NO (than in the above paradigm) has been elucidated.[77-79] Most notable is the covalent binding of NO^+ to cysteine thiols, forming S-nitrosothiols (SNOs). This paradigm developed following the discovery that endogenously produced NO circulated in human plasma primarily complexed to the protein albumin (S-nitrosoalbumin[80]), which transformed the understanding of bloodborne NO signaling. SNO proteins thus offered a means to conserve NO bioactivity, allowing the storage, transport, and potential release of NO remote from its location of synthesis.[81] The SNO hypothesis was extended to include a reactive thiol of Hb (Cysß93) that was demonstrated to undergo S-nitrosylation and sustain bioactivity under oxygenated conditions and NO release under low O_2 conditions (see HbSNO hypothesis).[56,57]

In this SNO paradigm, the NO radical must be oxidized to an NO^+ (nitrosonium) equivalent, which can then be passed between thiols in peptides and proteins, thereby preserving NO bioactivity.[77,78] S-nitrosylation then is akin to protein phosphorylation in terms of regulating protein function. SNO biochemistry offers NO a far broader signaling repertoire and has enabled awareness that the heme in sGC is not the sole, or even the principal, target of NO generated by endothelium. A wide array of alternative sGC (cyclic guanosine monophosphate)-independent reactions following endothelial NOS (eNOS) activation have been identified.[79,82]

Processing and Export of S-Nitrosothiols by Red Blood Cells

Hb S-nitrosylation (HbSNO), which has been characterized by both mass spectrometry[83] and x-ray crystallography,[84] provides an explanation as to how NO circumvents terminal reactions with Hb, enabling RBCs to conserve NO bioactivity and transport it throughout the circulation[56,57] (Fig. 89.5). The formation and export of NO groups by Hb is governed by the transition in Hb conformation that occurs in the course of O_2 loading/unloading during arteriovenous (A-V) transit. This is due to

conformational dependent change in reactivity of the Cysβ93 residue toward NO, which is higher in the R (oxygenated) Hb state and lower in the T (deoxygenated) Hb state.[56,57]

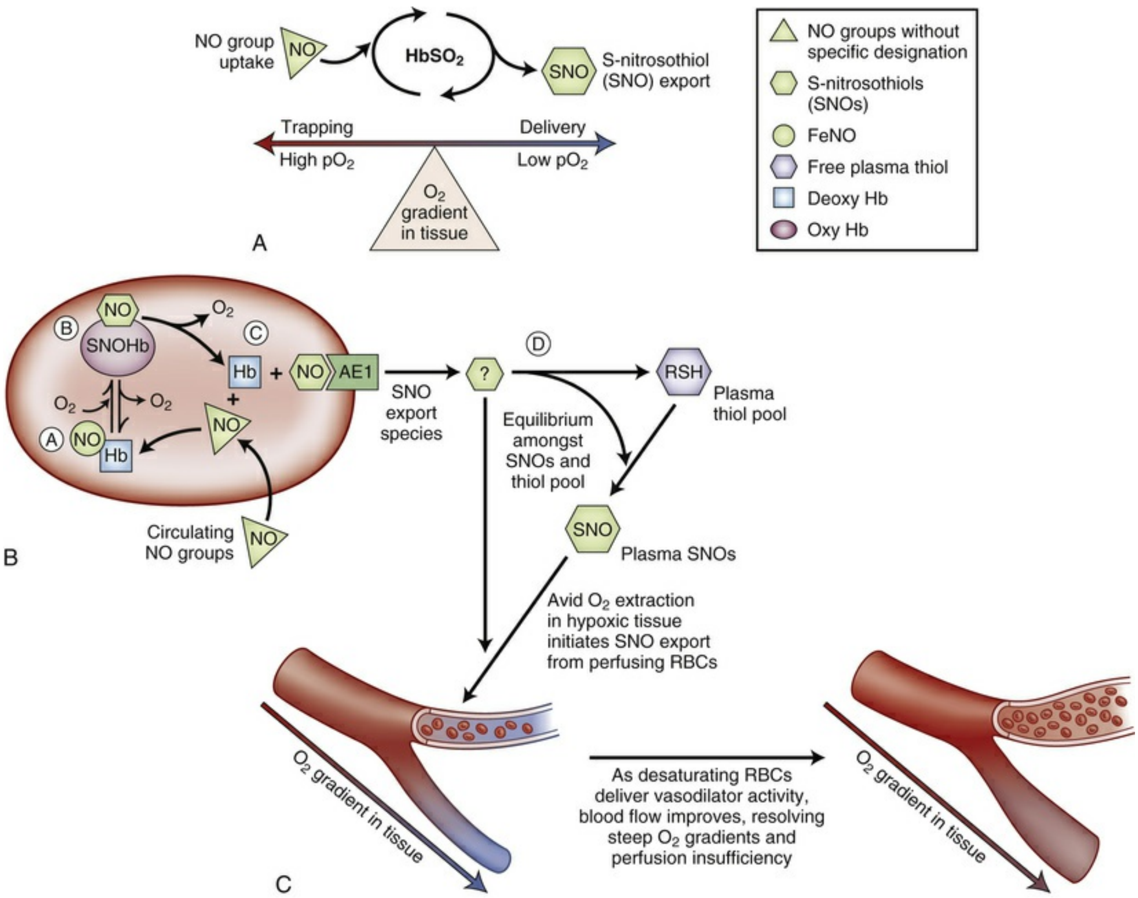

FIG. 89.5 RBCs transduce regional O_2 gradients in tissue to control nitric oxide (NO) bioactivity in plasma by trapping or delivering NO groups as a function of hemoglobin (Hb) O_2 saturation. (A) In this fashion, circulating NO groups are processed by Hb into the highly vasoactive (thiol-based) NO congener, S-nitrosothiol (SNO). By exporting SNOs as a function of Hb deoxygenation, RBCs precisely dispense vasodilator bioactivity in direct proportion to regional blood flow lack. (B) O_2 delivery homeostasis requires biochemical coupling of vessel tone to environmental cues that will match perfusion sufficiency to metabolic demand. Because oxy- and deoxy-Hb process NO differently (see the text), allosteric transitions in Hb conformation afford context-responsive (O_2-coupled) control of NO bioavailability, thereby linking the sensor and effector arms of this system. Specifically, Hb conformation governs the equilibria among deoxy-HbFeNO (A; NO sink), SNO-oxy-Hb (B; NO store), and acceptor thiols including the membrane protein SNO-AE-1 (C; bioactive NO source). Direct SNO export from RBCs or S-transnitrosylation from RBCs to plasma thiols (D) or to endothelial cells directly (not shown) yields vasoactive SNOs, which influence resistance vessel caliber and close this signaling loop. Thus, RBCs either trap (A) or export (D) NO groups to optimize blood flow. (C) NO processing in RBCs (A and B) couples vessel tone to tissue PO_2; this system subserves hypoxic vasodilation in the arterial periphery and thereby calibrates blood flow to regional tissue

hypoxia.

In a tightly regulated fashion, Hb captures and binds NO at its β-hemes and then passes the NO group from the heme to a thiol (Cys-β93-SNO).[70,85] Transfer of NO between heme and thiol requires heme-redox coupled activation of the NO group, which is controlled by O_2 capture-induced conformational transition across the lung.[86] Once in R state, the Cys-β93-SNO is protected through confinement to a hydrophobic pocket.[84] NO group export from Cys-β93-SNO occurs when steep O_2 gradients are encountered in the periphery (HVD). The R- to T-state conformational transition that occurs upon Cys-β93-SNO deoxygenation (or oxidation) results in a shift in the location of the β chain from its hydrophobic niche toward the aqueous cytoplasmic solvent.[84] This allows the Cys-β93-SNO to be "chemically available" for transfer to target thiol-containing proteins, including those associated with the RBC membrane protein AE-1 (Band 3)[87] and extra-erythrocytic thiols.[88,89] Resultant plasma or other cellular SNOs then become vasoactive at low nM concentrations.[56,57] Importantly, all NO transfers in this process involve NO^+,[56,58] which protects bioactivity from Fe^{2+} heme recapture or inactivation. S-nitrosothiols are the only known endogenous NO compounds that retain bioactivity in the presence of Hb.[56,89,90]

Extensive evidence supports SNO-Hb biology, whereby RBCs exert graded vasodilator and vasoconstrictor responses across the physiologic microcirculatory O_2 gradient. RBCs dilate preconstricted aortic rings at low PO_2 (1% O_2), while constricting at high PO_2 (95% O_2).[57,90-92] The vasodilatory response at low O_2 is enhanced following the addition of NO (or SNO) to RBCs, commensurate with SNO-Hb formation.[56,87,90,93] Additionally, the vasodilatory response is enhanced in the presence of extracellular free thiol,[90] occurs in the absence of endothelium[58,90] (which is consistent with in vivo observation that HVD is endothelium independent[94]), and transpires in the time frame of circulatory transit, as confirmed by measurements of A-V gradients in SNO-Hb.[56,88,91,92] In addition to these ex vivo experiments, numerous groups have also demonstrated bioactivity of inhaled NO, commensurate with SNO-Hb formation.[95-99]

Metabolism of Nitrite by Red Blood Cells

Nitrite (NO_2^-), formed mainly via hydration reactions involving *N*-oxides, was long viewed as an inactive oxidation product of NO metabolism. More recently it has been proposed as circulating pool of bioactive NO.[100] Some have suggested that the reduction of nitrite by deoxyHb may serve as the RBC-derived signaling mechanism regulating HVD.[101] However, this hypothesis has two major shortcomings in terms of known NO chemistry/biochemistry and HVD physiology. First, to influence vascular tone, the NO radical produced from NO_2^- must escape RBCs at low O_2 tension in order to elicit a vasodilatory response. Experimental evidence, however, unambiguously refutes the possibility of NO escaping RBCs as an authentic radical, especially given the proximity, high concentration, and rapid reaction kinetics ($10^7 M^{-1}s^{-1}$) of authentic NO with deoxyHb. The only plausible reconciliation would be that bioactivity from this reaction may derive from heme captured NO ($HbFe^{2+}NO$) being further converted into SNO-Hb,[70,85] as $HbFe^{2+}NO$ itself acts as a vasoconstrictor

rather than vasodilator.[102] The second shortcoming relates to the fact that the NO_2^- reductase activity of deoxyHb is purportedly symmetrical across the physiologic O_2 gradient,[103,104] with maximal activity occurring at the P_{50} of Hb (~27 mm Hg).[103,105] This reaction profile does not match the HVD response, which increases in a steadily graded fashion as PO_2 falls in the physiologic range from 100 mm Hg down to approximately 5 mm Hg ($HbSO_2$ ~1%-2%).[51,54] If RBC-based vasoactivity were maximal at Hb's P_{50}, then blood flow would be diverted away from regions with PO_2 below 27 mm Hg, where it would be needed most. Additionally, based on the symmetry of Hb nitrite reductase activity at the P_{50}, RBCs traversing vascular beds with PO_2 at 25 or 75 would generate equal NO-based activity,[101] whereas it should be obvious that at such gas tensions different blood flow demands are required.

Vasoregulation by Red Blood Cell–Derived Adenosine Triphosphate

Adenosine triphosphate (ATP) has long been known to act as an endothelium-dependent vasodilator in humans,[55] binding to P_2Y purinergic receptors to induce local and conducted vasodilation via stimulation of vasoactive signals including endothelial NO, prostaglandins, and endothelial-derived hyperpolarization factors (EDHFs). More recently, RBCs have been identified as sources of vascular ATP,[55,106] with release stimulated by conditions associated with diminished O_2 supply relative to demand, hypoxia, hypercapnia, and low pH.[55,107] O_2 offloading from membrane-associated Hb is thought to initiate RBC ATP release,[106] stimulating heterotrimeric G protein,[108] as a result of membrane deformation. This leads to activation of adenylyl cyclase and an increase in cAMP,[109] which activates protein kinase A (PKA).[109] PKA stimulates cystic fibrosis transmembrane conductance regulator (CFTR),[110] which activates release of ATP from the RBC via pannexin 1.[111] Release of ATP via this pathway requires an increase in intracellular cAMP, which is controlled by the relative activities of adenylyl cyclase and phosphodiesterase 3 (PDE3B).[60]

Despite potential as a HVD mediator, RBC-derived ATP falls short on two fronts. First, HVD is unaltered by both endothelial denudation and eNOS deletion[58]; however, ATP vasoactivity is endothelium dependent. Second, blood levels of ATP rise and fall over a period of minutes, which is not commensurate with the HVD response that occurs in the course of A-V transit over a couple of seconds. Despite its shortcomings in terms of acting as a primary mediator of HVD, it is likely that Hb and ATP serve complementary vasoactive roles, in acute local and prolonged systemic hypoxia, respectively.[58]

Energy Metabolism in Red Blood Cells

The mature RBC, devoid of the organelles and enzymes required for oxidative energy production, relies on the relatively inefficient anaerobic glycolytic pathway for ATP generation (Fig. 89.6). This pathway, also known as the Embden-Meyerhof pathway (EMP), shares the same initial substrate (glucose-6-phosphate; G6P) as its sister pathway the pentose shunt, otherwise known as the hexose monophosphate pathway (HMP). These two metabolic pathways fulfill different cellular

requirements. The EMP furnishes RBCs with ATP, 2,3-DPG (aiding in O_2 unloading), and NADH (necessary to reverse formation of metHb). The HMP ensures efficient NADPH recycling, necessary to maintain the antioxidant capacity required to protect RBCs from oxidative stress.

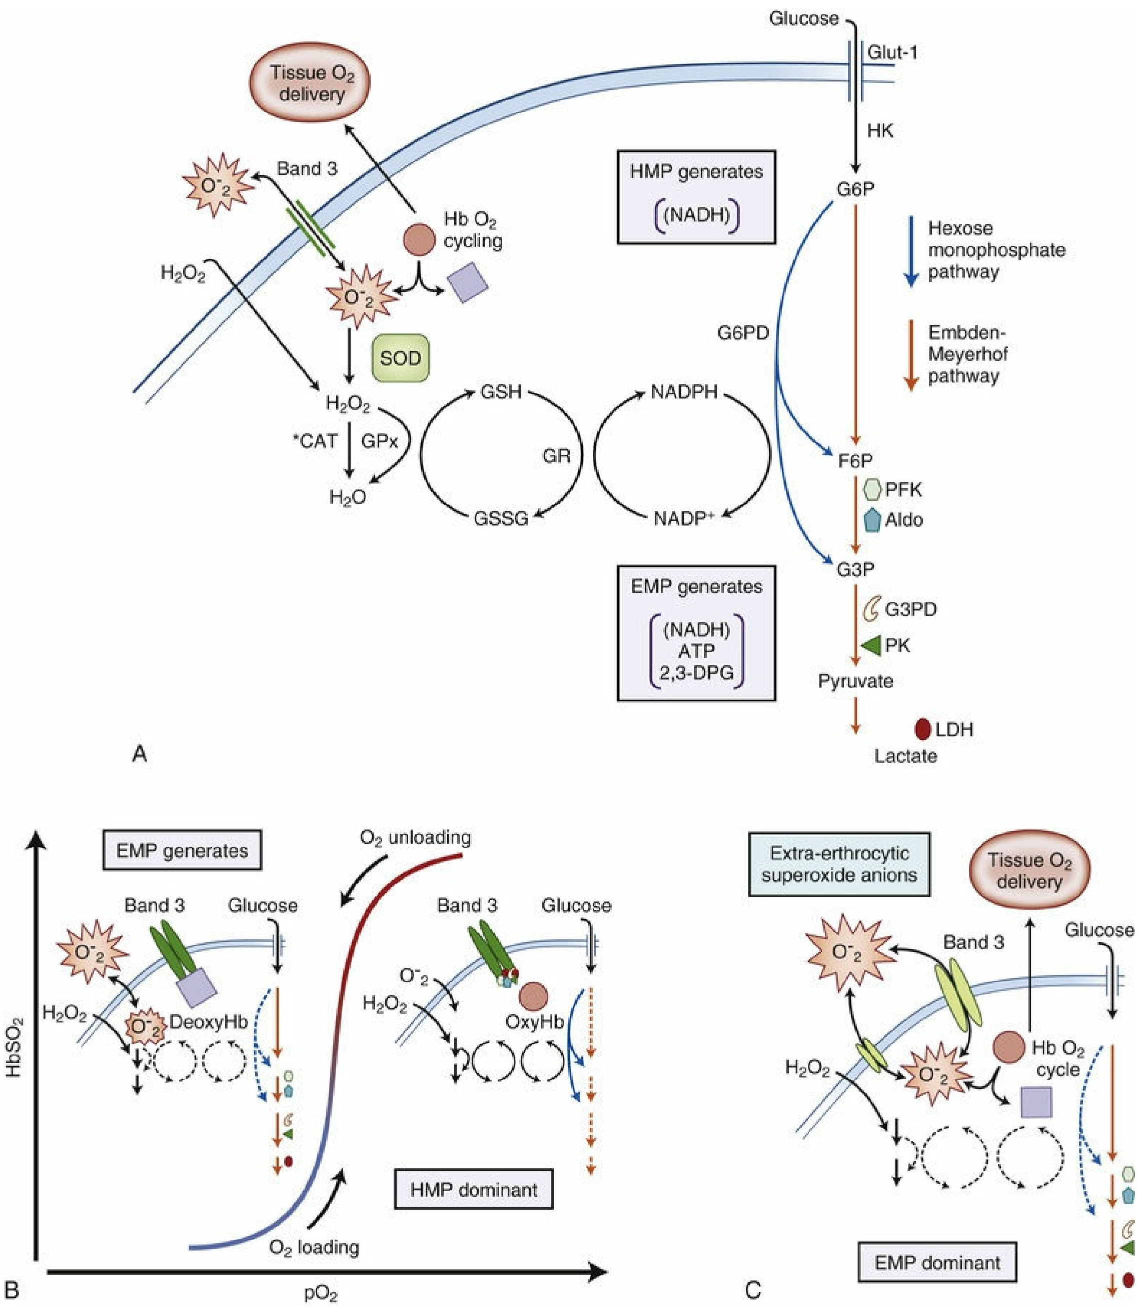

FIG. 89.6 Simplified scheme of cdB3-based control of RBC metabolism and proposed causal path for SiRD. (A) Energy metabolism in RBCs proceeds through either the Embden-Meyerhof pathway (EMP, *orange arrows*) or the hexose monophosphate pathway (HMP, *blue arrows,* also known as the "pentose shunt"). Both share glucose-6-phosphate (G6P) as initial substrate. The HMP is the sole source of NADPH in RBCs and generates fructose-6-phosphate (F6P) or glyceraldehyde-3-phosphate (G3P), which will rejoin the EMP prior to glyceraldehyde-3-phosphate dehydrogenase (G3PD/GAPDH), a key regulatory point. The EMP

generates NADH (utilized by metHb reductase), as well as ATP (to drive ion pumps) and 2,3-DPG (to modulate hemoglobin P_{50}). Hydrogen peroxide (H_2O_2) and superoxide anion (O_2^-) are the principal endogenous reactive O_2 species (ROS) that are generated/encountered by RBCs. Both ROS are generated internally in the course of HbO_2 cycling.[176-178] Notably, only H_2O_2 can cross the membrane directly. O_2^- enters/departs RBCs via the Band 3 channel (anion exchange protein 1, or AE-1). O_2^- and H_2O_2 are ultimately reduced to water by catalase (CAT) or glutathione peroxidase (GPx). (B) O_2 content modulates EMP/HMP balance via reciprocal binding for cdB3 between deoxyHb and key EMP enzymes (PFK, Aldo, G3PD, PK, and LDH). In oxygenated RBCs (right half of stylized O_2 dissociation plot), EMP enzyme sequestration to cdB3 inactivates this pathway, resulting in HMP dominance and maximal NADPH (and thus GSH) recycling capacity. In deoxygenated RBCs (left half of O_2 dissociation plot), deoxyHb binding to cdB3 disperses bound EMP enzymes, activating the EMP, creating G6P substrate competition, constraining HMP flux, limiting NADPH and GSH recycling capacity, and weakening resilience to ROS, such as O_2^-. (C) In sepsis, data suggest cdB3-complex assembly may be prevented (particularly, with coincident hypoxia, see text). As in settings similarly impacting the cdB3 complex, it appears that this disturbs normal EMP/HMP balance (disfavoring HMP), depowering antioxidant systems and rendering RBCs vulnerable to oxidant attack. *Aldo,* aldolase; *GSH,* glutathione; *GR,* glutathione reductase; *NADPH,* nicotinamide adenine dinucleotide phosphate; *PFK,* phosphofructokinase; *PK,* pyruvate kinase; *LDH,* lactate dehydrogenase.

Glucose is the principal RBC energy source; however, other substrates including inosine, fructose, mannose, and galactose can also be metabolized. Glucose enters RBCs by energy-independent facilitated diffusion via the insulin-independent glucose transporter GLUT-1. Upon entry, it is immediately phosphorylated to glucose-6-phosphate (G6P), thus preventing escape from RBCs.

Regulation of Red Blood Cell Energetics by Hemoglobin

Historically, the regulation of RBC energetics was thought to be under the control of covalent modifications or feedback inhibition/activation of key enzymes. However, more recently it has been demonstrated that RBC metabolism is under the control of an O_2-sensitive reciprocal binding relationship between key EMP enzymes and Hb for the cytoplasmic domain of the Band 3 (cdB3) membrane protein.[112-116] EMP enzyme binding to cdB3 is inhibitory, decelerating this pathway in oxygenated RBCs.[117,118] Specifically, it has been demonstrated that (1) deoxygenated Hb displays a higher affinity for cdB3 than oxygenated Hb,[119] (2) phosphorylation of specific tyrosine residues (positions 8 and 21) on cdB3 displaces EMP enzymes from the membrane,[112,120] and (3) tyrosine phosphorylation up-regulates the EMP and down-regulates the HMP.[121]

O_2-sensitive regulation of glucose flux perfectly suits RBC requirements. Under fully oxygenated conditions, inhibition of glycolytic enzymes (due to their binding to cdB3) releases substrate constraint on G6P, allowing greater HMP flux and ensuring efficient NADPH recycling, necessary to protect RBCs from oxidative stress derived from the high O_2 load/environment. Conversely, the displacement and activation of

EMP enzymes from cdB3 under low O_2 conditions up-regulates EMP activity, furnishing RBCs with ATP, 2,3-DPG (aiding in O_2 unloading), and NADH (necessary to reverse formation of metHb), which occurs subsequent to O_2 unloading.[114]

In unstressed conditions, 90% to 95 % of total erythrocytic glucose is metabolized via the EMP. Under such conditions, the G6PD reaction operates at less than 1% of its capacity,[122] largely due to inhibition of the enzyme by NADPH. Exposure of RBCs to oxidant stress results in the oxidation of NADPH (to $NADP^+$), releasing the inhibition on G6PD. In such situations, the HMP can account for 80% to 100% of total glucose consumed.[123,124] This ability to up-regulate the HMP serves to maintain levels of the reducing equivalent NADPH, which protects the cell by preserving functionality of several antioxidant systems. Loss of ability to accelerate EMP flux plays a significant role in RBC dysfunction in a variety of conditions, including critical illness.[125-127]

Role of Embden-Meyerhof Pathway

The 2 mol of ATP per mole of glucose generated via the RBC EMP is used almost exclusively in and on the plasma membrane to maintain electrochemical and ion gradients, phosphorylation reactions, and turnover of phospholipid phosphates. Cytosolic processes account for less than 10% of total ATP utilization.[128] These minor components include the maintenance of glycolysis and reduction reactions involving Hb, enzyme, and membrane protein sulfhydryls.

In addition to ATP generation, the EMP also generates the allosteric effector 2,3-diphosphoglycerate (2,3-DPG), via the subsidiary Luebering–Rapoport shunt (L-RS). 2,3-DPG stabilizes the deoxygenated Hb “T-state” conformation, thereby decreasing Hb affinity for O_2 and facilitating O_2 release to tissue, effectively raising P_{50}, or shifting the oxyhemoglobin dissociation curve to the right. Flux through the L-RS is O_2 and pH dependent: At an RBC intracellular physiologic pH of 7.2, this pathway accounts for approximately 20% of glycolytic flux. However, greater flux is observed in response to hypoxia and increases in pH. The glyceraldehyde phosphate dehydrogenase (GAPDH) reaction of the EMP also furnishes the cells with NADH, which is utilized by the enzyme methemoglobin reductase to reduce the heme group of Hb from its oxidized ferric state (Fe^{3+}) to its reduced ferrous state (Fe^{2+}),[129] thus maintaining the ability of Hb to reversibly bind O_2. This system maintains metHb concentrations in healthy individuals at less than 1% of total Hb.[128]

Role of Hexose Monophosphate Pathway

The HMP, which shares G6P (with the EMP) as initial substrate, does not generate any high-energy phosphate bonds. Instead, its primary function is reduction of $NADP^+$ to NADPH. This is achieved via the glucose-6-phosphate dehydrogenase (G6PD) reaction. The reducing equivalent NADPH is highly relevant in terms of cellular antioxidant capacity, as it serves as the electron source for several enzymes including glutathione reductase, catalase, and thioredoxin reductase, which are central to RBC antioxidant systems.

Red Blood Cells, Free Radicals, and Reactive Oxygen

Species

During circulation, RBCs encounter a variety of naturally produced free radicals. These chemical species, which contain one or more unpaired electrons, play a number of important signaling roles and include superoxide, O_2^-; hydroxyl radical, HO• ; and nitric oxide, NO•.[58,130] RBCs also encounter various reactive oxygen species (ROS), including nonradical derivatives of O_2 such as hydrogen peroxide (H_2O_2). Although low concentrations of these species are essential for normal function, uncontrolled accumulation is damaging. The specific fate of ROS in RBCs is subject to their specific reaction rates, reactant concentration, and competing reaction rates. Consequently, ROS compartmentalization plays a significant role in protection strategies. For example, uncharged molecules such as H_2O_2 freely cross the RBC membrane, whereas charged molecules such as O_2^- enter only via transmembrane anion channels. For this reason, O_2^- is often concentrated in the intracellular compartment. Additionally, H_2O_2 and O_2^- are more selective in terms of their reactivity with biological molecules. For example, the main reactions of O_2^- are with itself (dismutation), with other radical species, or with transition metals. On the other hand, HO• is a much more aggressive oxidizing species and reacts with numerous biological targets, making it potentially much more damaging.

By virtue of the environment to which they are exposed, which is rich in O_2 and heme-iron, RBCs are continuously exposed to oxidant stress. During reversible O_2 binding, occasional spontaneous conformational fluctuations in the heme pocket of oxygenated Hb allow water or a small anion to enter, resulting in transfer of an electron from the iron to O_2 to produce metHb and the O_2^- radical. In fact, approximately 2% to 3% of total Hb undergoes auto-oxidation daily.[104] In addition to scavenging endogenously produced oxidants, due to their ubiquitous distribution, RBCs are also ideally positioned to act as circulating detoxification agents, neutralizing other oxidants produced throughout the circulation.[131]

Red Blood Cell Antioxidant Systems

RBCs require robust antioxidant systems, with the ability to rapidly counter the detrimental effects of oxidative insult. Oxidant damage occurring to RBCs may result from either an increase in ROS production or a reduction in antioxidant capacity. Generally, such situations are mainly observed under pathologic conditions, leading to disruption of membrane transport systems, enzymes, proteins, and lipids and the premature removal of the RBC from the circulation. Classically, the RBC antioxidant system comprises components to scavenge and detoxify ROS and prevents generation of radical chain reactions.[132] However, additional secondary mechanisms are also important and selectively rid the RBC of damaged proteins,[133,134] thereby prolonging circulation time.

Several enzymatic antioxidants are found in RBCs, including superoxide dismutase (SOD), catalase (Cat), glutathione peroxidase (GSHPx), glutathione reductase (GR), periredoxin (Prx), TrxR, plasma membrane oxidoreductases (PMOR), and metHb reductase (metHbR). Ongoing functionality of these enzymatic antioxidant systems requires recycling of the reducing equivalents NADPH and NADH, which are recycled in RBCs via glucose metabolism through the HMP and

EMP, respectively.

In healthy RBCs, most metHb reduction is achieved through an NADH-linked system.[135] NADH, furnished via the EMP (glycolytic) pathway in the G3PD reaction, is utilized by the enzyme metHbR. NADH reduces cytochrome b_5, which in turn reduces the iron of metHb from its ferric trivalent (+3) state to its ferrous divalent (+2) state. GSH and ascorbic acid also play a role in metHb reduction, although their contribution is minimal. Ongoing functionality of metHbR requires metabolic flux via the EMP, which is the main route via which RBCs recycle NAD+ to its reduced form (NADH).

In addition to the enzymatic antioxidant systems, RBCs also contain numerous nonenzymatic antioxidants, including glutathione (GSH); vitamins A, C (ascorbate), and E (alpha tocopherol); and other less familiar species such as uric acid and melatonin.

GSH (L-y-glutamyl-L-cysteinylglycine) is the most abundant low-molecular-weight thiol found in RBCs (concentration ~2 mM). GSH can act as a direct scavenger of free radicals or as a substrate for GSHPx during the detoxification of H_2O_2 and lipid hydroperoxides. GSH also directly reduces protein sulfhydryls, generating glutathione disulfide (GSSG), which is recycled by GR. Steady-state GSH levels reflect a balance between synthesis (including both de novo synthesis and GR-mediated regeneration of GSH from GSSG) and loss due to GSSG efflux from the cell. The RBC membrane is permeable to GSSG, but not GSH. GSSG removal from the cell occurs as a result of active transport, in a process that is temperature sensitive and dependent on metabolic energy.[136,137] When the cell is no longer able to maintain GSH content, irreversible damage occurs.

Three vitamins (A, C, and E) provide important defense against oxidant stress in RBCs. Carotenoids, the precursors to vitamin A, also exert antioxidant effects in RBCs. In total, six carotenoid species have been detected in RBCs including lutein, zeaxanthin, β-cryptoxanthin, α-carotene, β-carotene, and lycopene. Vitamin C (ascorbic acid or ascorbate) readily donates one or two electrons to a variety of oxidants, including O_2 free radicals, peroxides, and superoxide. Additionally vitamin C functions to recycle vitamin E (alpha tocopherol) in a nonenzymatic pathway involving dihydrolipoic acid. Each stage of vitamin C oxidation is reversible, thus permitting recycling. RBCs lack an active transporter for vitamin C. Uptake occurs by simple diffusion and is consequently very slow, with a half-time of hours. Dehydroascorbic acid (DHA), however, is taken up by RBCs by facilitated diffusion through the glucose transporter (GLUT-1), after which it is rapidly converted to ascorbate and trapped within the cells.[138] RBCs also have enzymes that can facilitate GSH-dependent reduction of DHA, including the thioltransferase glutaredoxin. Vitamins A and E are both lipophilic and reside in the RBC membrane. Vitamin E acts as the major radical chain-breaking antioxidant. In the process of scavenging lipid and nonlipid radical species, vitamin E is oxidized to a tocopheroxyl radical. This radical can be recycled back to vitamin E in an NADH cytochrome b_5-dependent reaction or via a nonenzymatic pathway involving vitamin C. Melatonin (*N*-acetyl-5-methoxytryptamine), the chief secretory product of the pineal gland, is also synthesized in RBCs. This synthetic product functions as a direct ROS scavenger for O_2^-, H_2O_2, and HO•, in addition to lipid peroxides. Furthermore, melatonin has also been demonstrated to stimulate other antioxidant enzymes, including Cu-Zn-

SOD, catalase, GSHPx, glutathione reductase, and G6PD.

Acquired Red Blood Cell Injury, Eryptosis, and Clearance

After maturation to an anucleated cell furnished with the metabolic systems described earlier, the estimated normal life span of a mature RBC is 110 to 120 days.[139] To date, clearance of normal senescent RBC is not clearly understood. Two mechanisms have been proposed, clustering of the Band 3 (B3) membrane protein[140-143] and externalization of membrane phosphatidyl serine (PS),[144-147] both of these processes may be accelerated in the setting of critical illness, impairing oxygen transport capacity. Oxidatively modified hemoglobin (Hb) forms hemichrome aggregates, which associate with the cytoplasmic domain of the abundant membrane protein B3. Subsequent clustering of B3 exofascial domains increases affinity of naturally occurring anti-B3 autoantibodies, which activate the complement system, leading to RBC uptake and destruction by macrophages.[148] Normally, PS is asymmetrically distributed in the plasma membrane (a process regulated by flippases). Disruption of this pattern is a well-documented mark of RBC senescence,[144-147] signaling RBC removal by the reticuloendothelial system.[147] Alternatively, RBCs may proceed through a form of “stimulated suicide” similar to apoptosis (termed *eryptosis*), which is characterized by cell shrinkage and cell membrane scrambling that is stimulated by Ca^{2+} entry through Ca^{2+}-permeable, PGE_2-activated cation channels, by ceramide, caspases, calpain, complement, hyperosmotic shock, energy depletion, oxidative stress, and deranged activity of several kinases (eg, AMPK, GK, PAK_2, CK1α, JAK_3, PKC, p38-MAPK). Eryptosis has been described in the setting of ethanol intoxication, malignancy, hepatic failure, diabetes, chronic renal insufficiency, hemolytic uremic syndrome, dehydration, phosphate depletion, fever, sepsis, mycoplasma infection, malaria, iron deficiency, sickle cell anemia, thalassemia, G6PD deficiency, and Wilson disease.[147,149,150]

Blood Flow Disruption During Critical Illness by Maladaptive Red Blood Cell–Based Signaling

Evidence is mounting in support of a causal relationship between acquired RBC dysfunction and a host of perfusion-related morbidities that complicates critical illness.[20,92,151-165] It has been observed that levels of SNO-Hb are altered in several disease states characterized by disordered tissue oxygenation.[92,93,166-173] In addition, where examined, RBCs from such patients exhibit impaired vasodilatory capacity.[88,92,93,170,172-174] These data suggest that altered RBC-derived NO bioactivity may contribute to human pathophysiology. Specifically, alterations in thiol-based RBC NO metabolism have been reported in congestive heart failure,[92] diabetes,[93,169] pulmonary hypertension,[91,168] and sickle cell disease,[170,175] all of which are conditions characterized by inflammation, oxidative stress, and dysfunctional vascular control. Moreover, known cross-talk between SNO signaling and cellular communication via carbon monoxide, serotonin, prostanoids, catecholamines, and endothelin may permit broad dispersal of signals initiated by dysfunctional RBCs. Precise

understanding of the roles of dysregulated RBC-based NO transport in the spread of vasomotor dysfunction in stressed vascular beds may open novel therapeutic approaches to a range of pathologies.

CHAPTER 90

Hemoglobinopathies

M.A. Bender, Gabrielle Douthitt Seibel

PEARLS

- The pathophysiology of sickle cell disease is multifactorial, involving hemoglobin polymerization, oxidative damage to cell membrane proteins, white blood cell activation and inflammation, activation of the clotting cascade, and chronic hemolysis resulting in disturbances in nitric oxide metabolism.
- Acute chest syndrome is responsible for up to 25% of deaths in sickle cell disease, and its management should include antibiotic therapy with both a cephalosporin and a macrolide, oxygen to maintain saturations greater than 94%, prevention of atelectasis with incentive spirometry and potential biphasic positive airway pressure, diligent fluid management, adequate pain control, and bronchodilators.
- The default should always be to trust a patient's self-assessment of sickle cell pain.
- Up to 30% of patients with sickle cell disease have pulmonary hypertension, and the threshold to treat must be lower than for other etiologies as even mild elevations in pulmonary arterial pressure (>25 mm Hg) correlate with a significantly increased risk of death.
- A major cause of death in thalassemia major is cardiac failure secondary to iron overload; therefore a thalassemic patient presenting with cardiac failure must be assessed for cardiac iron content and, if present, undergo continuous chelation therapy.

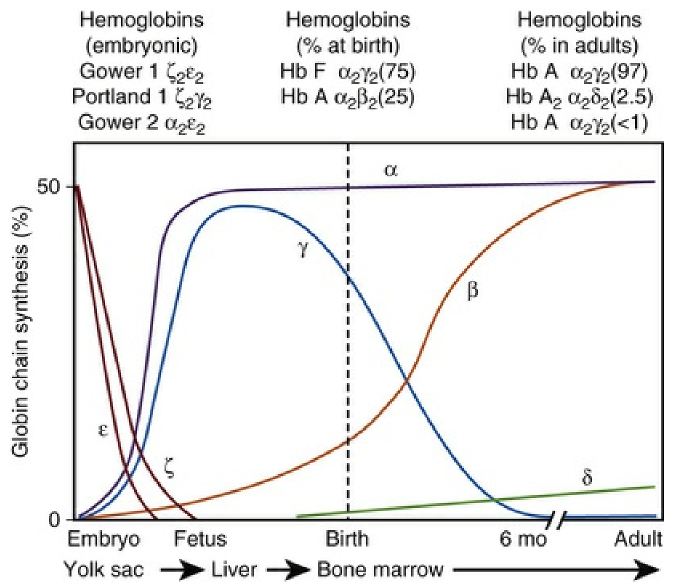
Perspective

The evolution of animals is dependent on high concentrations of hemoglobin in red cells, which relies on the extraordinarily robust and coordinated synthesis of the α- and β-like globin polypeptide chains and iron-containing heme rings. Each has a highly evolved structure essential for optimal pairing of α- and β-like chains, as unpaired peptides are unstable and initiate cellular damage. The resultant $\alpha2\beta2$ hemoglobin plays a critical role in the transport and regulation of carbon dioxide, pH, and nitric oxide (NO) in addition to O_2. Thus hemoglobin synthesis is a high-stakes process in which any mutation may affect hemoglobin production, stability,

function, or result in unpaired globin chains leading to devastating downstream effects. The approach to any hemoglobin alterations must consider the qualitative effects (how the plethora of hemoglobin's functions are altered) and quantitative effects (the amount of hemoglobin and unpaired globin chains).

Globin Gene Loci

The α- and β-like genes reside within multigene loci and are transcribed at unparalleled levels in both tightly tissue-specific and developmentally specific patterns.[1] This, and their involvement in human disease, has made these loci paradigms for gene regulation and pathophysiology. The five genes of the β-globin locus reside in a cluster on chromosome 11. The genes are expressed in an erythroid and developmentally stage-specific manor, the ε, Aγ and Gγ, and δ and β genes being expressed primarily during the embryonic, fetal, and postnatal periods, respectively. At birth, the majority of β-like chains are γ and the rest are β. This ratio inverts during the first year of life, explaining why phenotypes limited to the β-globin gene such as sickle cell and most β-thalassemias often do not manifest until several months of age. Expression of the chromosome 16–based α-like genes differs; the embryonic ζ-gene parallels the expression of ε, but the twin α-genes are expressed from the fetal period onward. Thus α abnormalities manifest in utero, potentially with devastating consequences (eg, hydrops fetalis). The resultant hemoglobin α-, β-heterotetramers (Hb) are developmentally expressed (eFig. 90.1).



EFIG. 90.1 Hemoglobin changes through development. Expression patterns of individual α-like (ζ and α) and β-like (ε, γ, δ, and β) chains are plotted through development. The resultant hemoglobins present at various developmental stages and a rough estimate of their abundances are listed above. See text for full details. (From Hoffman R, et al. Pathobiology of the human erythrocyte and its hemoglobins. In: Hematology: Basic Principles and Practice. 5th ed. 90 Elsevier; 2008. Copyright Elsevier 2008.)

Sickle Cell Disease

Molecular Description and Epidemiology

Sickle cell disease (SCD) refers to a group of single gene, autosomal recessive disorders most common in people originating from specific regions of Africa or India and in those of Hispanic descent. SCD encompasses a group of disorders characterized by the presence of the sickle mutation (substitution of an adenine [A] for a thymidine [T] in codon 6) and a second abnormal allele allowing the sickle hemoglobin to polymerize. This mutation results in replacement of a hydrophilic glutamic acid residue with a hydrophobic valine residue. With deoxygenation, allosteric changes in hemoglobin expose a destabilizing valine-containing pocket that aligns with others, leading to polymerization (crystallization), transition to the classic sickle cell morphology (Fig. 90.1), and the initiation of downstream events leading to pain and chronic end-organ damage (Fig. 90.2). In the United States, approximately 1 in 12 and 1 in 500 African Americans have sickle trait and SCD, respectively, with approximately 100,000 cases and approximately 2000 new birth cases per year (in contrast to approximately 200,000 birth cases per year in Africa). With increased ethnic mixing, compound heterozygous forms of SCD are increasingly being observed (eg, S/β-thalassemia or HbS/E).

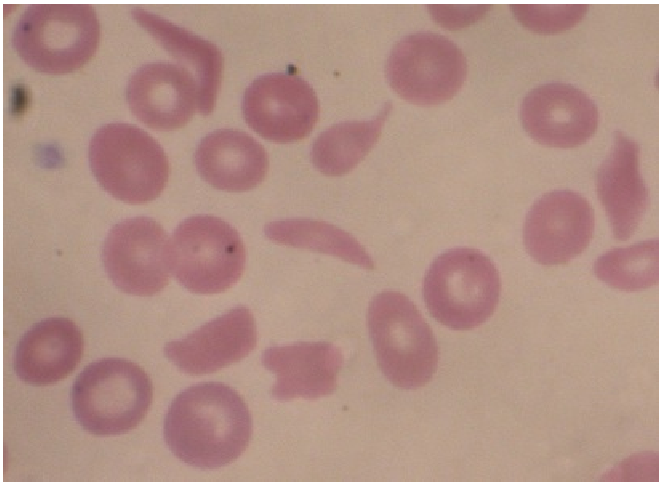


FIG. 90.1 Morphology of sickled cells. Note that although a subset of cells has a high degree of polymerized HbS and has taken on the classic sickle shape, the majority of cells maintain normal morphology. (Courtesy Dr. Min Xu, Seattle Children's Hospital.)

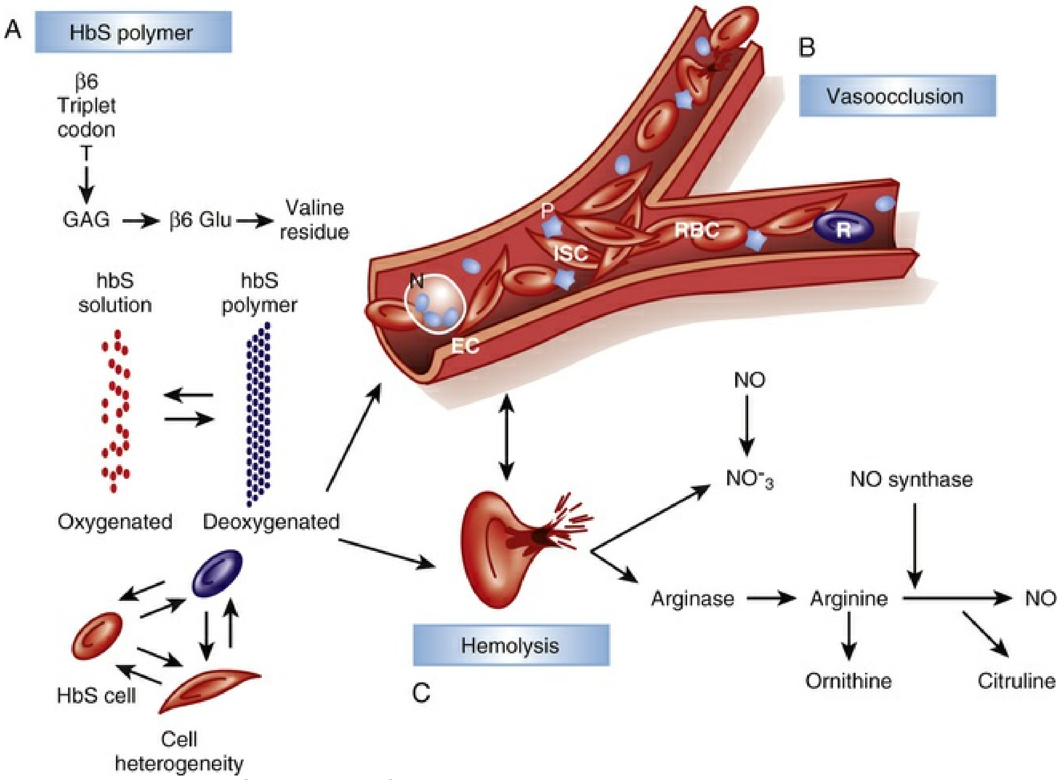

FIG. 90.2 Summary of multiple interacting steps contributing to the pathophysiology of sickle cell disease. Although this is an oversimplification and additional pathways are involved, the three predominant pathophysiologic steps are summarized. (A) Polymerization of HbS. A single nucleotide change results in HbS, which polymerizes upon prolonged deoxygenation, leading to sickled cells. (B) Red cells, inflammation, and the endothelium. Activation of adherence receptors, coagulation, platelet aggregation, and inflammatory pathways lead to slowed flow, increased capillary transit time, sickling of red blood cells, and eventual occlusion of blood flow. (*EC,* endothelial cell; *ISC,* irreversibly sickled cell; *N,* neutrophil; *P,* platelet; *RBC,* red blood cell; *R,* reticulocyte.) (C) Hemolysis and NO homeostasis. Hemolysis releases free hemoglobin, which breaks down NO, whereas release of arginase converts the substrate for NO, arginine, to ornithine. Thus less NO is generated and more is destroyed. (Modified courtesy Dr. Martin Steinberg, Boston University School of Medicine.)

Sickle Cell Trait

Sickle cell trait (SCT) is distinguished from SCD by the presence of a normal β-globin allele and more HbA than HbS (typically 40% HbS) (Table 90.1). SCT does not result in the classic spectrum of sickle-related complications or alter red cell indices, but it can lead to clinical abnormalities.[2,3] Most notable is the concern that extremes of aerobic physical exertion, dehydration, and humidity may induce sudden death in rare student athletes with sickle cell trait.[3,4]

TABLE 90.1

Hematologic Characteristics of Sickle Hemoglobinopathies

Diagnosis[a]	Predominant Hemoglobins After Age 1 Year[b]	Phenotype[c]	HEMATOLOGIC STUDIES AFTER AGE 1 YEAR[d]		
			Hgb	MCV[e]	HbA_2 (%)[f]
HbA	A	nl	nl	nl	nl
HbA/S (trait)	A > S[g]	nl[h]	nl	nl	nl
HbS/S	S	Hemolysis and anemia by age 6-12 mo	↓↓	nl	nl
HbS/β^0-thalassemia	S	Hemolysis and anemia by age 6-12 mo	↓↓	↓↓	nl or ↑
HbS/β^+-thalassemia	S > A	Milder hemolysis and anemia	↓	↓	nl or ↑
HbS/C	S ≅ C	Milder hemolysis and anemia	↓	nl or ↓	nl
HbS/E	S > E	Milder hemolysis and anemia[i]	↓	↓	nl[j]

[a]The β-thalassemias are divided into β^+-thalassemia, in which reduced levels of normal β-globin chains are produced, and β^0-thalassemia, in which there is no β-globin chain synthesis.

[b]Hemoglobins are reported in order of quantity. Only the most prominent hemoglobins are listed.

[c]Overview of phenotype.

[d]Values vary during the first year of life. Some patient's values continue to change after age 1 year.

[e]Must use age-specific values. MCV can be lowered by α-thalassemia trait and increased by hydroxyurea.

[f]HbA_2 results vary depending on laboratory method.

[g]In sickle trait, HbS is ~40% of total hemoglobins.

[h]Although patients do not have severe sequela, patients may have subtle abnormalities.

[i]Although patients have hemolysis and anemia, the severity of sickle cell–related complications tends to be less than HbS/C.

[j]Although HbA_2 is typically normal, this is often difficult to discern as HbE and HbA2 comigrate in some assays.

Table shows typical results; exceptions occur.

Hb, hemoglobin type; *Hgb,* hemoglobin concentration; *nl,* normal; ↑, increased; ↓, decreased; ↓↓, significantly decreased.

Spectrum of Sickle Cell Disease Genotypes and Natural History

The clinical manifestations of SCD result from intermittent episodes of vascular occlusion leading to tissue ischemia/reperfusion injury and variable degrees of hemolysis, both of which contribute to multiorgan dysfunction. Although homozygous sickle cell (Hb S/S, often called sickle cell anemia) is most common, it is essential to be aware of additional genotypes that result in a spectrum of disease severity (see Table 90.1) and that the spectrum of manifestations change with age.[5]

Laboratory and Diagnostics

The prominence of HbS in conjunction with diminished or absent HbA defines SCD. Several forms of electrophoresis or high-pressure liquid chromatography are most often used diagnostically but are rarely available on an emergent basis. HbS

screening tests (eg, Sickledex, Sickleprep, or Sicklequick) make use of the relative insolubility of deoxygenated HbS and are available emergently; however, results must be interpreted with extreme caution as they lack sensitivity and specificity.[6] Although imperfect, screening tests in conjunction with a complete blood count, smear, and measure of iron status (eg, zinc-protoporphyrin) help distinguish between SCD and SCT. Therefore in the setting of significant clinical suspicion of a hemoglobinopathy, consultation with lab medicine and hematology is recommended.

Pathophysiology

Although unable to fully provide the elegant details of the rapidly evolving insights into the multifaceted pathophysiology of SCD, this chapter outlines key pathways with direct relevance to management basics. Even though the initial era of understanding pathophysiology focused on HbS polymerization and red cell "sickling," this was followed by an awareness of the critical role of endothelial interactions, inflammation, and, later, of hemolysis and perturbations of NO metabolism (see Fig. 90.2).[7-12]

Hemoglobin Polymerization

The aforementioned crystallization of hemoglobin is enhanced by a high hemoglobin concentration (mean corpuscular hemoglobin concentration [MCHC]), low pH, and low temperature, whereas HbA and HbF attenuate it. A key determinant of sickling is the capillary transit time (CTT). The longer a red cell is exposed to the relatively deoxygenated, cold, and acidotic environment of the capillary and postcapillary venule, the more time exists for HbS polymerization to occur. This drives the basics of patient education, prevention, and medical management including hydration, warmth, avoiding acidosis and vasoconstriction, ambulation, and assuring oxygenation. It also is the rationale for inducers of HbF and agents to prevent cell dehydration.

Red Cells, Inflammation, and the Endothelium

Crystallization ultimately leads to deformation of erythrocytes and oxidative damage to cell membrane proteins, the activation of pathways contributing to the stimulation of white cells and inflammation, endothelial damage, and the initiation of the clotting cascade and platelet aggregation. Membrane damage triggers movement of phosphatidylserine to the outer leaf of the red cell membrane where it acts as a substrate for factor V and VIII binding, promoting the clotting cascade. Reticulocytes and sickled cells expose increased adherence proteins, increasing CTT and enhancing binding to other cell types. Binding to platelets results in their activation and aggregation, whereas binding to neutrophils stimulates the oxidative burst, damaging endothelium and exposing tissue factor, further promoting coagulation, platelet aggregation, and clot formation. Bound white cells release cytokines, increasing inflammatory cell recruitment and division and thereby perpetuating the process. Thus sickle cell represents an activated, inflammatory state in which the CTT is prolonged, propagating the cycle. This activation and

integration of multiple pathways explains the tremendous clinical heterogeneity observed in people with the same hemoglobin genotype, as well as why patients can show rapid clinical decline (Fig. 90.3). Consistent with the clinical importance of these pathways, an elevated white blood cell (WBC) count is a risk factor for pain episodes, acute chest syndrome, and early death.[13,14] Therapeutically, this points to the benefits of nonsteroidal antiinflammatory drugs (NSAIDs) in affecting the underlying pathophysiology as well as providing analgesia and why clinical response to hydroxyurea is correlated with a decrease in WBC count.[15,16]

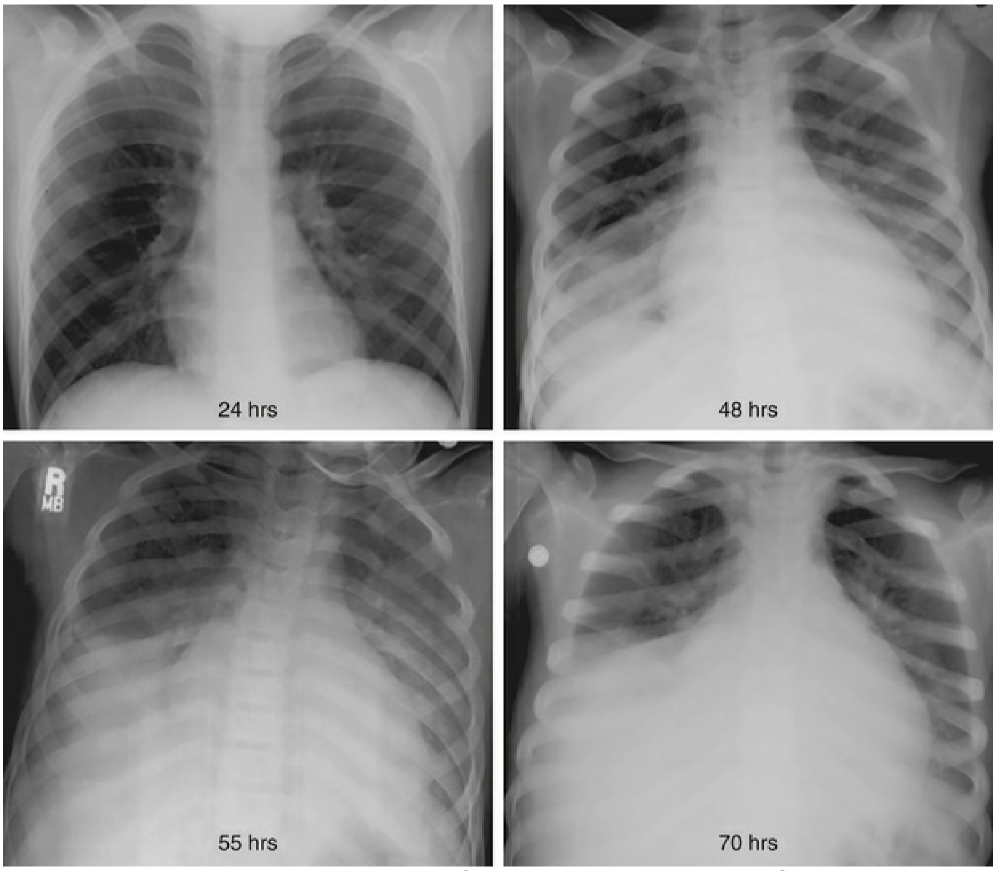

FIG. 90.3 Rapid progression of acute chest syndrome. Serial chest radiographs of a 13-year-old male with homozygous sickle cell disease admitted for pain. Hours from admission are noted. Notably acute chest syndrome typically presents 2 to 3 days into an admission for a vasoocclusive event.

Hemolysis and Nitric Oxide Homeostasis

In contrast to the vasoocclusive complications that correlate with a high WBC count and diminished HbF, a subset of complications—including pulmonary hypertension, skin ulcers, and priapism—was found to correlate with increased lactate dehydrogenase and bilirubin and reticulocyte count and is associated with a hemolytic phenotype arising and disturbances in NO hemostasis.[8-10,12] Hemolysis releases red blood cell (RBC) sequestered hemoglobin (Fe^{++}), allowing it to diffuse to the site of NO production (the endothelium) where it catalyzes the destruction of

NO several thousand-fold, decreasing NO to nitrate metabolism with resultant formation of methemoglobin (Fe^{+++}). In addition, hemolysis releases arginase, depleting arginine, the precursor for NO synthesis. Thus chronic hemolysis leads to decreased NO synthesis and increased destruction, resulting in altered NO hemostasis and increased tone of small vessels, slowing flow, and increasing sickling. Optimal management of hemolysis-related pathophysiology remains uncertain. Hemolysis prevention with hydroxyurea is appropriate and well accepted. NO metabolism is directly modified with class 5 phosphodiesterase inhibitors (eg, sildenafil) or by administering NO, its precursors, or related metabolites, approaches being actively investigated for both acute and chronic use.[12]

Clinical Manifestations

Although a summary of clinical problems and management is listed in the following section, the reader is referred to the National Heart Lung and Blood Institute standard of care guidelines[17] for more details (http://www.nhlbi.nih.gov/health-pro/guidelines/sickle-cell-disease-guidelines).

Pain

See eFig. 90.2 for a detailed care plan and eFigs. 90.3 and 90.4 for overviews of pain management.[18] Pain management in SCD is particularly difficult, as there are numerous etiologies (eg, vasoocclusive events [VOEs], dactylitis, avascular necrosis, acute chest syndrome, priapism, splenic sequestration and infarcts, hepatic crisis, and leg ulcers) and pathways involved (eg vasoocclusion, inflammation, and alterations in pain processing).[19-26] VOEs, defined as the acute onset of severe pain due to ischemia and reperfusion injury, are a hallmark of SCD. The complexities of SCD pain are best summarized by Shapiro and Ballas: "Vaso-occlusion is a physiologic process, but the resultant pain is a biopsychosocial phenomenon. Psychosocial issues such as coping skills, social context, personality, mood, and interactions with the health care system mingle with the biologic factors and contribute to the expression of the illness."[27] In the ICU, there must be an awareness of potential alterations in pain processing as well as awareness of the acute, neuropathic, inflammatory, psychologic, and social-cultural components of pain. Too often there is a primary focus opiate receptor blockade to the exclusion of addressing the inflammatory and neuropathic components. Pain can be acute, recurrent, or persistent, and it is complicated by coexisting chronic disease and racial overlays.[19-21,28] Too often racial attitudes and concerns of drug seeking prevent sufficient medication delivery to patients in excruciating pain.[28,29] The need for aggressive and rapid treatment is critical and well documented in guidelines of the American Pain Society and British Society of Hematology and is essential for humane care and physiologic improvements (eg, improving respiratory mechanics when having rib infarct pain).[30-32]

VASO-OCCLUSIVE PAIN

Diagnosis	Monitoring	Diagnostic (if not previously obtained)	Fluids, nutrition, general care	Medications/treatments	Discharge criteria
